Administering IBM MQ

Administering queue managers and associated resources includes the tasks that you perform frequently to activate and manage those resources. Choose the method you prefer to administer your queue managers and associated resources.

You can administer IBM® MQ objects locally or remotely, see “Local and remote administration” on page 4.

There are a number of different methods that you can use to create and administer your queue managers and their related resources in IBM MQ. These methods include command-line interfaces, a graphical user interface, and an administration API. See the sections and links in this topic for more information about each of these interfaces.

There are different sets of commands that you can use to administer IBM MQ depending on your platform:
- “IBM MQ control commands”
- “IBM MQ Script (MQSC) commands”
- “Programmable Command Formats (PCFs)” on page 2
- IBM i “IBM i Control Language (CL)” on page 3

There are also the other following options for creating and managing IBM MQ objects:
- “The MQ Explorer” on page 3
- “The Windows Default Configuration application” on page 3
- “The Microsoft Cluster Service (MSCS)” on page 3

z/OS For information about the administration interfaces and options on IBM MQ for z/OS®, see “Administering IBM MQ for z/OS” on page 255.

You can automate some administration and monitoring tasks for both local and remote queue managers by using PCF commands. These commands can also be simplified through the use of the IBM MQ Administration Interface (MQAI) on some platforms. For more information about automating administration tasks, see “Automating administration tasks” on page 5.

IBM MQ control commands

Control commands allow you to perform administrative tasks on queue managers themselves.

IBM MQ for Windows, UNIX and Linux systems provides the *control commands* that you issue at the system command line.

The control commands are described in Creating and managing queue managers on distributed platforms. For the command reference for the control commands, see IBM MQ Control commands.

IBM MQ Script (MQSC) commands

Use MQSC commands to manage queue manager objects, including the queue manager itself, queues, process definitions, namelists, channels, client connection channels, listeners, services, and authentication information objects.

You issue MQSC commands to a queue manager by using the **runmqsc** command. You can do this interactively, issuing commands from a keyboard, or you can redirect the standard input device (stdin) to run a sequence of commands from an ASCII text file. In both cases, the format of the commands is the same.

You can run the **runmqsc** command in three modes, depending on the flags set on the command:
- *Verification mode*, where the MQSC commands are verified on a local queue manager, but are not run
- *Direct mode*, where the MQSC commands are run on a local queue manager
- *Indirect mode*, where the MQSC commands are run on a remote queue manager

Object attributes specified in MQSC commands are shown in this section in uppercase (for example, RQMNAME), although they are not case-sensitive. MQSC command attribute names are limited to eight characters.

MQSC commands are available on all platforms z/OS IBM i , including IBM i, and z/OS . MQSC commands are summarized in Comparing command sets.

On Windows, UNIX or Linux, you can use the MQSC as single commands issued at the system command line. To issue more complicated, or multiple commands, the MQSC can be built into a file that you run from the Windows, UNIX or Linux system command line. MQSC can be sent to a remote queue manager. For full details, see Building command scripts.

IBM i On IBM i, to issue the commands on an IBM i server, create a list of commands in a Script file, and then run the file by using the STRMQMMQSC command.

Notes: IBM i
1. Do not use the QTEMP library as the input library to STRMQMMQSC, as the usage of the QTEMP library is limited. You must use another library as an input file to the command.
2. On IBM i, MQSC responses to commands issued from a script file are returned in a spool file.

"Script (MQSC) Commands" on page 74 contains a description of each MQSC command and its syntax.

See "Performing local administration tasks using MQSC commands" on page 73 for more information about using MQSC commands in local administration.

Programmable Command Formats (PCFs)

Programmable Command Formats (PCFs) define command and reply messages that can be exchanged between a program and any queue manager (that supports PCFs) in a network. You can use PCF commands in a systems management application program for administration of IBM MQ objects: authentication information objects, channels, channel listeners, namelists, process definitions, queue managers, queues, services, and storage classes. The application can operate from a single point in the network to communicate command and reply information with any queue manager, local, or remote, using the local queue manager.

For more information about PCFs, see "Introduction to Programmable Command Formats" on page 6.

For definition of PCFs and structures for the commands and responses, see Programmable command formats reference.

IBM i

IBM i Control Language (CL)

This language can be used to issue administration commands to IBM MQ for IBM i. The commands can be issued either at the command line or by writing a CL program. These commands perform similar functions to PCF commands, but the format is different. CL commands are designed exclusively for servers and CL responses are designed to be human-readable, whereas PCF commands are platform independent and both command and response formats are intended for program use.

For full details of the IBM i Control Language (CL), see IBM MQ for IBM i CL commands.

The MQ Explorer

Using the MQ Explorer, you can perform the following actions:
- Define and control various resources including queue managers, queues, process definitions, namelists, channels, client connection channels, listeners, services, and clusters.
- Start or stop a local queue manager and its associated processes.
- View queue managers and their associated objects on your workstation or from other workstations.
- Check the status of queue managers, clusters, and channels.
- Check to see which applications, users, or channels have a particular queue open, from the queue status.

On Windows and Linux systems, you can start MQ Explorer by using the system menu, the `MQExplorer` executable file, or the **`strmqcfg`** command.

On Linux, to start the MQ Explorer successfully, you must be able to write a file to your home directory, and the home directory must exist.

See “Administration using the MQ Explorer” on page 56 for more information.

You can use MQ Explorer to administer remote queue managers on other platforms including z/OS, for details and to download the SupportPac MS0T, see http://www.ibm.com/support/docview.wss?uid=swg24021041.

The Windows Default Configuration application

You can use the Windows Default Configuration program to create a *starter* (or default) set of IBM MQ objects. A summary of the default objects created is listed in Table 1: Objects created by the Windows default configuration application.

The Microsoft Cluster Service (MSCS)

Microsoft Cluster Service (MSCS) enables you to connect servers into a *cluster*, giving higher availability of data and applications, and making it easier to manage the system. MSCS can automatically detect and recover from server or application failures.

It is important not to confuse clusters in the MSCS sense with IBM MQ clusters. The distinction is:

IBM MQ clusters
are groups of two or more queue managers on one or more computers, providing automatic interconnection, and allowing queues to be shared among them for load balancing and redundancy.

MSCS clusters
Groups of computers, connected together and configured in such a way that, if one fails, MSCS performs a *failover*, transferring the state data of applications from the failing computer to another computer in the cluster and reinitiating their operation there.

Supporting the Microsoft Cluster Service (MSCS) provides detailed information about how to configure your IBM MQ for Windows system to use MSCS.

Local and remote administration

You can administer IBM MQ objects locally or remotely.

Local administration means carrying out administration tasks on any queue managers you have defined on your local system. You can access other systems, for example through the TCP/IP terminal emulation program **telnet**, and carry out administration there. In IBM MQ, you can consider this as local administration because no channels are involved, that is, the communication is managed by the operating system.

IBM MQ supports administration from a single point of contact through what is known as *remote administration*. This allows you to issue commands from your local system that are processed on another system and applies also to the IBM MQ Explorer. For example, you can issue a remote command to change a queue definition on a remote queue manager. You do not have to log on to that system, although you do need to have the appropriate channels defined. The queue manager and command server on the target system must be running.

Some commands cannot be issued in this way, in particular, creating or starting queue managers and starting command servers. To perform this type of task, you must either log onto the remote system and issue the commands from there or create a process that can issue the commands for you. This restriction applies also to the IBM MQ Explorer.

"Administering remote IBM MQ objects" on page 129 describes the subject of remote administration in greater detail.

How to use IBM MQ control commands

This section describes how to use the IBM MQ control commands.

If you want to issue control commands, your user ID must be a member of the mqm group. For more information about this, see Authority to administer IBM MQ on UNIX, Linux and Windows systems. In addition, note the following environment-specific information:

IBM MQ for Windows

All control commands can be issued from a command line. Command names and their flags are not case sensitive: you can enter them in uppercase, lowercase, or a combination of uppercase and lowercase. However, arguments to control commands (such as queue names) are case sensitive.

In the syntax descriptions, the hyphen (-) is used as a flag indicator. You can use the forward slash (/) instead of the hyphen.

IBM MQ for UNIX and Linux systems

All IBM MQ control commands can be issued from a shell. All commands are case-sensitive.

A subset of the control commands can be issued using the IBM MQ Explorer.

For more information, see The IBM MQ control commands

Automating administration tasks

You might decide that it would be beneficial to your installation to automate some administration and monitoring tasks. You can automate administration tasks for both local and remote queue managers using programmable command format (PCF) commands. This section assumes that you have experience of administering IBM MQ objects.

PCF commands

IBM MQ programmable command format (PCF) commands can be used to program administration tasks into an administration program. In this way, from a program you can manipulate queue manager objects (queues, process definitions, namelists, channels, client connection channels, listeners, services, and authentication information objects), and even manipulate the queue managers themselves.

PCF commands cover the same range of functions provided by MQSC commands. You can write a program to issue PCF commands to any queue manager in the network from a single node. In this way, you can both centralize and automate administration tasks.

Each PCF command is a data structure that is embedded in the application data part of an IBM MQ message. Each command is sent to the target queue manager using the MQI function **MQPUT** in the same way as any other message. Providing the command server is running on the queue manager receiving the message, the command server interprets it as a command message and runs the command. To get the replies, the application issues an **MQGET** call and the reply data is returned in another data structure. The application can then process the reply and act accordingly.

Note: Unlike MQSC commands, PCF commands and their replies are not in a text format that you can read.

Briefly, these are some of the things needed to create a PCF command message:

Message descriptor

This is a standard IBM MQ message descriptor, in which:

- Message type (`MsqType`) is MQMT_REQUEST.

- Message format (*Format*) is MQFMT_ADMIN.

Application data
Contains the PCF message including the PCF header, in which:
- The PCF message type (*Type*) specifies MQCFT_COMMAND.
- The command identifier specifies the command, for example, *Change Queue* (MQCMD_CHANGE_Q).

For a complete description of the PCF data structures and how to implement them, see “Introduction to Programmable Command Formats.”

PCF object attributes

Object attributes in PCF are not limited to eight characters as they are for MQSC commands. They are shown in this guide in italics. For example, the PCF equivalent of RQMNAME is *RemoteQMgrName*.

Escape PCFs

Escape PCFs are PCF commands that contain MQSC commands within the message text. You can use PCFs to send commands to a remote queue manager. For more information about escape PCFs, see Escape.

Introduction to Programmable Command Formats

Programmable Command Formats (PCFs) define command and reply messages that can be exchanged between a program and any queue manager (that supports PCFs) in a network. PCFs simplify queue manager administration and other network administration. They can be used to solve the problem of complex administration of distributed networks especially as networks grow in size and complexity.

The Programmable Command Formats described in this product documentation are supported by:
- IBM MQ for AIX®
- IBM MQ for HP-UX
- IBM i IBM MQ for IBM i
- IBM MQ for Linux
- IBM MQ for Solaris
- IBM MQ for Windows
- z/OS IBM MQ for z/OS
- IBM IBM WebSphere® MQ for HP Integrity NonStop Server V5.3

The problem PCF commands solve

The administration of distributed networks can become complex. The problems of administration continue to grow as networks increase in size and complexity.

Examples of administration specific to messaging and queuing include:
- Resource management.

  For example, queue creation and deletion.
- Performance monitoring.

  For example, maximum queue depth or message rate.
- Control.

  For example, tuning queue parameters such as maximum queue depth, maximum message length, and enabling and disabling queues.

- Message routing.

  Definition of alternative routes through a network.

IBM MQ PCF commands can be used to simplify queue manager administration and other network administration. PCF commands allow you to use a single application to perform network administration from a single queue manager within the network.

What are PCFs?

PCFs define command and reply messages that can be exchanged between a program and any queue manager (that supports PCFs) in a network. You can use PCF commands in a systems management application program for administration of IBM MQ objects: authentication information objects, channels, channel listeners, namelists, process definitions, queue managers, queues, services, and storage classes. The application can operate from a single point in the network to communicate command and reply information with any queue manager, local, or remote, using the local queue manager.

Each queue manager has an administration queue with a standard queue name and your application can send PCF command messages to that queue. Each queue manager also has a command server to service the command messages from the administration queue. PCF command messages can therefore be processed by any queue manager in the network and the reply data can be returned to your application, using your specified reply queue. PCF commands and reply messages are sent and received using the normal Message Queue Interface (MQI).

For a list of the available PCF commands, including their parameters, see Definitions of the Programmable Command Formats.

Using Programmable Command Formats

You can use PCFs in a systems management program for IBM MQ remote administration.

This section includes:

- “PCF command messages”
- “Responses” on page 10
- z/OS “Extended responses” on page 12
- Rules for naming IBM MQ objects
- “Authority checking for PCF commands” on page 14

PCF command messages:

PCF command messages consist of a PCF header, parameters identified in that header and also user-defined message data. The messages are issued using Message Queue interface calls.

Each command and its parameters are sent as a separate command message containing a PCF header followed by a number of parameter structures; for details of the PCF header, see MQCFH - PCF header, and for an example of a parameter structure, see MQCFST - PCF string parameter. The PCF header identifies the command and the number of parameter structures that follow in the same message. Each parameter structure provides a parameter to the command.

Replies to the commands, generated by the command server, have a similar structure. There is a PCF header, followed by a number of parameter structures. Replies can consist of more than one message but commands always consist of one message only.

On platforms other than z/OS, the queue to which the PCF commands are sent is always called the SYSTEM.ADMIN.COMMAND.QUEUE. z/OS On z/OS, commands are sent to SYSTEM.COMMAND.INPUT, although SYSTEM.ADMIN.COMMAND.QUEUE can be an alias for it. The command server servicing this queue sends the replies to the queue defined by the *ReplyToQ* and *ReplyToQMgr* fields in the message descriptor of the command message.

How to issue PCF command messages

Use the normal Message Queue Interface (MQI) calls, MQPUT, MQGET, and so on, to put and retrieve PCF command and response messages to and from their queues.

Note:

Ensure that the command server is running on the target queue manager for the PCF command to process on that queue manager.

For a list of supplied header files, see IBM MQ COPY, header, include and module files.

Message descriptor for a PCF command

The IBM MQ message descriptor is fully documented in MQMD - Message descriptor.

A PCF command message contains the following fields in the message descriptor:

Report
: Any valid value, as required.

MsgType
: This field must be MQMT_REQUEST to indicate a message requiring a response.

Expiry
: Any valid value, as required.

Feedback
: Set to MQFB_NONE

Encoding
: If you are sending to ▶ IBM i IBM i, Windows, UNIX or Linux systems, set this field to the encoding used for the message data; conversion is performed if necessary.

CodedCharSetId
: If you are sending to

  ▶ IBM i IBM i, Windows, UNIX or Linux systems, set this field to the coded character-set identifier used for the message data; conversion is performed if necessary.

Format
: Set to MQFMT_ADMIN.

Priority
: Any valid value, as required.

Persistence
: Any valid value, as required.

MsgId
: The sending application can specify any value, or MQMI_NONE can be specified to request the queue manager to generate a unique message identifier.

CorrelId
: The sending application can specify any value, or MQCI_NONE can be specified to indicate no correlation identifier.

ReplyToQ
: The name of the queue to receive the response.

ReplyToQMgr
The name of the queue manager for the response (or blank).

Message context fields
These fields can be set to any valid values, as required. Normally the Put message option MQPMO_DEFAULT_CONTEXT is used to set the message context fields to the default values.

If you are using a version-2 MQMD structure, you must set the following additional fields:

GroupId
Set to MQGI_NONE

MsgSeqNumber
Set to 1

Offset
Set to 0

MsgFlags
Set to MQMF_NONE

OriginalLength
Set to MQOL_UNDEFINED

Sending user data

The PCF structures can also be used to send user-defined message data. In this case the message descriptor *Format* field must be set to MQFMT_PCF.

Sending and receiving PCF messages in a specified queue:

Sending PCF messages to a specified queue

To send a message to a specified queue, the mqPutBag call converts the contents of the specified bag into a PCF message and sends the message to the specified queue. The contents of the bag are left unchanged after the call.

As input to this call, you must supply:
- An MQI connection handle.
- An object handle for the queue on which the message is to be placed.
- A message descriptor. For more information about the message descriptor, see MQMD - Message descriptor.
- Put Message Options using the MQPMO structure. For more information about the MQPMO structure, see MQPMO - Put-message options.
- The handle of the bag to be converted to a message.

  Note: If the bag contains an administration message and the mqAddInquiry call was used to insert values into the bag, the value of the MQIASY_COMMAND data item must be an INQUIRE command recognized by the MQAI.

For a full description of the mqPutBag call, see mqPutBag.

Receiving PCF messages from a specified queue

To receive a message from a specified queue, the mqGetBag call gets a PCF message from a specified queue and converts the message data into a data bag.

As input to this call, you must supply:

- An MQI connection handle.
- An object handle of the queue from which the message is to be read.
- A message descriptor. Within the MQMD structure, the `Format` parameter must be MQFMT_ADMIN, MQFMT_EVENT, or MQFMT_PCF.

  Note: If the message is received within a unit of work (that is, with the MQGMO_SYNCPOINT option) and the message has an unsupported format, the unit of work can be backed out. The message is then reinstated on the queue and can be retrieved using the MQGET call instead of the mqGetBag call. For more information about the message descriptor, see MQGMO - Get-message options.
- Get Message Options using the MQGMO structure. For more information about the MQGMO structure, see MQMD - Message Descriptor.
- The handle of the bag to contain the converted message.

For a full description of the mqGetBag call, see mqGetBag.

Responses:

In response to each command, the command server generates one or more response messages. A response message has a similar format to a command message.

The PCF header has the same command identifier value as the command to which it is a response (see MQCFH - PCF header for details). The message identifier and correlation identifier are set according to the report options of the request.

If the PCF header type of the command message is MQCFT_COMMAND, standard responses only are generated. Such commands are supported on all platforms except z/OS. Older applications do not support PCF on z/OS ; the IBM MQ Windows Explorer is one such application (however, the Version 6.0 or later IBM MQ Explorer does support PCF on z/OS).

If the PCF header type of the command message is MQCFT_COMMAND_XR, either extended or standard responses are generated. Such commands are supported on z/OS and some other platforms. Commands issued on z/OS generate only extended responses. On other platforms, either type of response might be generated.

If a single command specifies a generic object name, a separate response is returned in its own message for each matching object. For response generation, a single command with a generic name is treated as multiple individual commands (except for the control field MQCFC_LAST or MQCFC_NOT_LAST). Otherwise, one command message generates one response message.

Certain PCF responses might return a structure even when it is not requested. This structure is shown in the definition of the response (Definitions of the Programmable Command Formats) as *always returned*. The reason that, for these responses, it is necessary to name the objects in the response to identify which object the data applies.

Message descriptor for a response

A response message has the following fields in the message descriptor:

MsgType
: This field is MQMT_REPLY.

MsgId
: This field is generated by the queue manager.

CorrelId
: This field is generated according to the report options of the command message.

Format
This field is MQFMT_ADMIN.

Encoding
Set to MQENC_NATIVE.

CodedCharSetId
Set to MQCCSI_Q_MGR.

Persistence
The same as in the command message.

Priority
The same as in the command message.

The response is generated with MQPMO_PASS_IDENTITY_CONTEXT.

Standard responses:

Command messages with a header type of MQCFT_COMMAND, standard responses are generated. Such commands are supported on all platforms except z/OS.

There are three types of standard response:
- OK response
- Error response
- Data response

OK response

This response consists of a message starting with a command format header, with a *CompCode* field of MQCC_OK or MQCC_WARNING.

For MQCC_OK, the *Reason* is MQRC_NONE.

For MQCC_WARNING, the *Reason* identifies the nature of the warning. In this case the command format header might be followed by one or more warning parameter structures appropriate to this reason code.

In either case, for an inquire command further parameter structures might follow as described in the following sections.

Error response

If the command has an error, one or more error response messages are sent (more than one might be sent even for a command that would normally have only a single response message). These error response messages have MQCFC_LAST or MQCFC_NOT_LAST set as appropriate.

Each such message starts with a response format header, with a *CompCode* value of MQCC_FAILED and a *Reason* field that identifies the particular error. In general, each message describes a different error. In addition, each message has either zero or one (never more than one) error parameter structures following the header. This parameter structure, if there is one, is an MQCFIN structure, with a *Parameter* field containing one of the following:
- MQIACF_PARAMETER_ID

  The *Value* field in the structure is the parameter identifier of the parameter that was in error (for example, MQCA_Q_NAME).
- MQIACF_ERROR_ID

This value is used with a *Reason* value (in the command format header) of MQRC_UNEXPECTED_ERROR. The *Value* field in the MQCFIN structure is the unexpected reason code received by the command server.

- MQIACF_SELECTOR

  This value occurs if a list structure (MQCFIL) sent with the command contains a duplicate selector or one that is not valid. The *Reason* field in the command format header identifies the error, and the *Value* field in the MQCFIN structure is the parameter value in the MQCFIL structure of the command that was in error.
- MQIACF_ERROR_OFFSET

  This value occurs when there is a data compare error on the Ping Channel command. The *Value* field in the structure is the offset of the Ping Channel compare error.
- MQIA_CODED_CHAR_SET_ID

  This value occurs when the coded character-set identifier in the message descriptor of the incoming PCF command message does not match that of the target queue manager. The *Value* field in the structure is the coded character-set identifier of the queue manager.

The last (or only) error response message is a summary response, with a *CompCode* field of MQCC_FAILED, and a *Reason* field of MQRCCF_COMMAND_FAILED. This message has no parameter structure following the header.

Data response

This response consists of an OK response (as described earlier) to an inquire command. The OK response is followed by additional structures containing the requested data as described in Definitions of the Programmable Command Formats.

Applications must not depend upon these additional parameter structures being returned in any particular order.

Extended responses:

Commands issued on z/OS generate extended responses.

There are three types of extended response:
- Message response, with type MQCFT_XR_MSG
- Item response, with type MQCFT_XR_ITEM
- Summary response, with type MQCFT_XR_SUMMARY

Each command can generate one, or more, sets of responses. Each set of responses comprises one or more messages, numbered sequentially from 1 in the *MsgSeqNumber* field of the PCF header. The *Control* field of the last (or only) response in each set has the value MQCFC_LAST. For all other responses in the set, this value is MQCFC_NOT_LAST.

Any response can include one, or more, optional MQCFBS structures in which the *Parameter* field is set to MQBACF_RESPONSE_SET, the value being a response set identifier. Identifiers are unique and identify the set of responses which contain the response. For every set of responses, there is an MQCFBS structure that identifies it.

Extended responses have at least two parameter structures:
- An MQCFBS structure with the *Parameter* field set to MQBACF_RESPONSE_ID. The value in this field is the identifier of the set of responses to which the response belongs. The identifier in the first set is arbitrary. In subsequent sets, the identifier is one previously notified in an MQBACF_RESPONSE_SET structure.

- An MQCFST structure with the *Parameter* field set to MQCACF_RESPONSE_Q_MGR_NAME, the value being the name of the queue manager from which the set of responses come.

Many responses have additional parameter structures, and these structures are described in the following sections.

You cannot determine in advance how many responses there are in a set other than by getting responses until one with MQCFC_LAST is found. Neither can you determine in advance how many sets of responses there are as any set might include MQBACF_RESPONSE_SET structures to indicate that additional sets are generated.

Extended responses to Inquire commands

Inquire commands normally generate an item response (type MQCFT_XR_ITEM) for each item found that matches the specified search criteria. The item response has a *CompCode* field in the header with a value of MQCC_OK, and a *Reason* field with a value of MQRC_NONE. It also includes other parameter structures describing the item and its requested attributes, as described in Definitions of the Programmable Command Formats.

If an item is in error, the *CompCode* field in the header has a value of MQCC_FAILED and the *Reason* field identifies the particular error. Additional parameter structures are included to identify the item.

Certain Inquire commands might return general (not name-specific) message responses in addition to the item responses. These responses are informational, or error, responses of the type MQCFT_XR_MSG.

If the Inquire command succeeds, there might, optionally, be a summary response (type MQCFT_XR_SUMMARY), with a *CompCode* value of MQCC_OK, and a *Reason* field value of MQRC_NONE.

If the Inquire command fails, item responses might be returned, and there might optionally be a summary response (type MQCFT_XR_SUMMARY), with a *CompCode* value of MQCC_FAILED, and a *Reason* field value of MQRCCF_COMMAND_FAILED.

Extended responses to commands other than Inquire

Successful commands generate message responses in which the *CompCode* field in the header has a value of MQCC_OK, and the *Reason* field has a value of MQRC_NONE. There is always at least one message; it might be informational (MQCFT_XR_MSG) or a summary (MQCFT_XR_SUMMARY). There might optionally be additional informational (type MQCFT_XR_MSG) messages. Each informational message might include a number of additional parameter structures with information about the command; see the individual command descriptions for the structures that can occur.

Commands that fail generate error message responses (type MQCFT_XR_MSG), in which the *CompCode* field in the header has a value of MQCC_FAILED and the *Reason* field identifies the particular error. Each message might include a number of additional parameter structures with information about the error: see the individual error descriptions for the structures that can occur. Informational message responses might be generated. There might, optionally, be a summary response (MQCFT_XR_SUMMARY), with a *CompCode* value of MQCC_FAILED, and a *Reason* field value of MQRCCF_COMMAND_FAILED.

Extended responses to commands using CommandScope

If a command uses the *CommandScope* parameter, or causes a command using the *CommandScope* parameter to be generated, there is an initial response set from the queue manager where the command was received. Then a separate set, or sets, of responses is generated for each queue manager to which the command is directed (as if multiple individual commands were issued). Finally, there is a response set from the receiving queue manager which includes an overall summary response (type MQCFT_XR_SUMMARY). The MQCACF_RESPONSE_Q_MGR_NAME parameter structure identifies the queue manager that generates each set.

The initial response set has the following additional parameter structures:
- MQIACF_COMMAND_INFO (MQCFIN). Possible values in this structure are MQCMDI_CMDSCOPE_ACCEPTED or MQCMDI_CMDSCOPE_GENERATED.
- MQIACF_CMDSCOPE_Q_MGR_COUNT (MQCFIN). This structure indicates the number of queue managers to which the command is sent.

Authority checking for PCF commands:

When a PCF command is processed, the `UserIdentifier` from the message descriptor in the command message is used for the required IBM MQ object authority checks. Authority checking is implemented differently on each platform as described in this topic.

The checks are performed on the system on which the command is being processed; therefore this user ID must exist on the target system and have the required authorities to process the command. If the message has come from a remote system, one way of achieving the ID existing on the target system is to have a matching user ID on both the local and remote systems.

IBM i

IBM MQ for IBM i

In order to process any PCF command, the user ID must have *dsp* authority for the IBM MQ object on the target system.

In addition, IBM MQ object authority checks are performed for certain PCF commands, as shown in Table 1 on page 16.

In most cases these checks are the same checks as those checks performed by the equivalent IBM MQ CL commands issued on a local system. See the Setting up security on IBM i , for more information about the mapping from IBM MQ authorities to IBM i system authorities, and the authority requirements for the IBM MQ CL commands. Details of security concerning exits are given in the Link level security using a security exit documentation.

To process any of the following commands the user ID must be a member of the group profile QMQMADM:
- Ping Channel
- Change Channel
- Copy Channel
- Create Channel
- Delete Channel
- Reset Channel
- Resolve Channel
- Start Channel
- Stop Channel
- Start Channel Initiator
- Start Channel Listener

Windows UNIX Linux

IBM MQ for Windows, UNIX and Linux systems

In order to process any PCF command, the user ID must have *dsp* authority for the queue manager object on the target system. In addition, IBM MQ object authority checks are performed for certain PCF commands, as shown in Table 1 on page 16.

To process any of the following commands the user ID must belong to group *mqm*.

Note: For Windows **only**, the user ID can belong to group *Administrators* or group *mqm*.

- Change Channel
- Copy Channel
- Create Channel
- Delete Channel
- Ping Channel
- Reset Channel
- Start Channel
- Stop Channel
- Start Channel Initiator
- Start Channel Listener
- Resolve Channel
- Reset Cluster
- Refresh Cluster
- Suspend Queue Manager
- Resume Queue Manager

IBM MQ for HP Integrity NonStop Server

In order to process any PCF command, the user ID must have *dsp* authority for the queue manager object on the target system. In addition, IBM MQ object authority checks are performed for certain PCF commands, as shown in Table 1 on page 16.

To process any of the following commands the user ID must belong to group *mqm*:

- Change Channel
- Copy Channel
- Create Channel
- Delete Channel
- Ping Channel
- Reset Channel
- Start Channel
- Stop Channel
- Start Channel Initiator
- Start Channel Listener
- Resolve Channel
- Reset Cluster
- Refresh Cluster
- Suspend Queue Manager
- Resume Queue Manager

IBM MQ Object authorities

IBM i IBM i, UNIX and Linux systems - object authorities

Table 1. Windows, HP Integrity NonStop Server,

Command	**IBM MQ object authority**	**Class authority (for object type)**
Change Authentication Information	dsp and chg	n/a
Change Channel	dsp and chg	n/a
Change Channel Listener	dsp and chg	n/a
Change Client Connection Channel	dsp and chg	n/a
Change Namelist	dsp and chg	n/a
Change Process	dsp and chg	n/a
Change Queue	dsp and chg	n/a
Change Queue Manager	chg *see Note 3 and Note 5*	n/a
Change Service	dsp and chg	n/a
Clear Queue	clr	n/a
Copy Authentication Information	dsp	crt
Copy Authentication Information (Replace) *see Note 1*	*from:* dsp *to:* chg	crt
Copy Channel	dsp	crt
Copy Channel (Replace) *see Note 1*	*from:* dsp *to:* chg	crt
Copy Channel Listener	dsp	crt
Copy Channel Listener (Replace) *see Note 1*	*from:* dsp *to:* chg	crt
Copy Client Connection Channel	dsp	crt
Copy Client Connection Channel (Replace) *see Note 1*	*from:* dsp *to:* chg	crt
Copy Namelist	dsp	crt
Copy Namelist (Replace) *see Note 1*	*from:* dsp *to:* dsp and chg	crt
Copy Process	dsp	crt
Copy Process (Replace) *see Note 1*	*from:* dsp *to:* chg	crt
Copy Queue	dsp	crt
Copy Queue (Replace) *see Note 1*	*from:* dsp *to:* dsp and chg	crt
Create Authentication Information	*(system default authentication information)* dsp	crt
Create Authentication Information (Replace) *see Note 1*	*(system default authentication information)* dsp *to:* chg	crt
Create Channel	*(system default channel)* dsp	crt
Create Channel (Replace) *see Note 1*	*(system default channel)* dsp *to:* chg	crt
Create Channel Listener	*(system default listener)* dsp	crt
Create Channel Listener (Replace) *see Note 1*	*(system default listener)* dsp *to:* chg	crt
Create Client Connection Channel	*(system default channel)* dsp	crt
Create Client Connection Channel (Replace) *see Note 1*	*(system default channel)* dsp *to:* chg	crt

Table 1. Windows, HP Integrity NonStop Server, (continued)

Command	**IBM MQ object authority**	**Class authority (for object type)**
Create Namelist	*(system default namelist)* dsp	crt
Create Namelist (Replace) *see Note 1*	*(system default namelist)* dsp *to:* dsp and chg	crt
Create Process	*(system default process)* dsp	crt
Create Process (Replace) *see Note 1*	*(system default process)* dsp *to:* chg	crt
Create Queue	*(system default queue)* dsp	crt
Create Queue (Replace) *see Note 1*	*(system default queue)* dsp *to:* dsp and chg	crt
Create Service	*(system default queue)* dsp	crt
Create Service (Replace) *see Note 1*	*(system default queue)* dsp *to:* chg	crt
Delete Authentication Information	dsp and dlt	n/a
Delete Authority Record	*(queue manager object)* chg *see Note 4*	*see Note 4*
Delete Channel	dsp and dlt	n/a
Delete Channel Listener	dsp and dlt	n/a
Delete Client Connection Channel	dsp and dlt	n/a
Delete Namelist	dsp and dlt	n/a
Delete Process	dsp and dlt	n/a
Delete Queue	dsp and dlt	n/a
Delete Service	dsp and dlt	n/a
Inquire Authentication Information	dsp	n/a
Inquire Authority Records	*see Note 4*	*see Note 4*
Inquire Channel	dsp	n/a
Inquire Channel Listener	dsp	n/a
Inquire Channel Status (for **ChannelType** MQCHT_CLSSDR)	inq	n/a
Inquire Client Connection Channel	dsp	n/a
Inquire Namelist	dsp	n/a
Inquire Process	dsp	n/a
Inquire Queue	dsp	n/a
Inquire Queue Manager	*see note 3*	n/a
Inquire Queue Status	dsp	n/a
Inquire Service	dsp	n/a
Ping Channel	ctrl	n/a
Ping Queue Manager	*see note 3*	n/a
Refresh Queue Manager	(queue manager object) chg	n/a
Refresh Security (for **SecurityType** MQSECTYPE_SSL)	(queue manager object) chg	n/a
Reset Channel	ctrlx	n/a
Reset Queue Manager	(queue manager object) chg	n/a
Reset Queue Statistics	dsp and chg	n/a
Resolve Channel	ctrlx	n/a
Set Authority Record	*(queue manager object)* chg *see Note 4*	*see Note 4*

Table 1. Windows, HP Integrity NonStop Server, (continued)

Command	**IBM MQ object authority**	**Class authority (for object type)**
Start Channel	ctrl	n/a
Stop Channel	ctrl	n/a
Stop Connection	(queue manager object) chg	n/a
Start Listener	ctrl	n/a
Stop Listener	ctrl	n/a
Start Service	ctrl	n/a
Stop Service	ctrl	n/a
Escape	*see Note 2*	*see Note 2*

Notes:

1. This command applies if the object to be replaced does exist, otherwise the authority check is as for Create, or Copy without Replace.
2. The required authority is determined by the MQSC command defined by the escape text, and it is equivalent to one of the previous commands.
3. In order to process any PCF command, the user ID must have dsp authority for the queue manager object on the target system.
4. This PCF command is authorized unless the command server has been started with the -a parameter. By default the command server starts when the Queue Manager is started, and without the -a parameter. See the System Administration Guide for further information.
5. Granting a user ID *chg* authority for a queue manager gives the ability to set authority records for all groups and users. Do not grant this authority to ordinary users or applications.

IBM MQ also supplies some channel security exit points so that you can supply your own user exit programs for security checking. Details are given in Displaying a channel manual.

z/OS

IBM MQ for z/OS

See Task 1: Identify the z/OS system parameters for information about authority checking on z/OS.

Using the MQAI to simplify the use of PCFs

The MQAI is an administration interface to IBM MQ that is available on the AIX, HP-UX, IBM i, Linux, Solaris, and Windows platforms.

The MQAI performs administration tasks on a queue manager through the use of *data bags*. Data bags allow you to handle properties (or parameters) of objects in a way that is easier than using PCFs.

The advantages of using the MQAI are as follows:

Simplify the use of PCF messages

The MQAI is an easier way to administer IBM MQ. If you use the MQAI, you do not have to write your own PCF messages. This avoids the problems associated with complex data structures.

To pass parameters in programs written using MQI calls, the PCF message must contain the command, and details of the string or integer data. To create this configuration manually, you have to add several statements in your program for every structure, and you have to allocate memory space. This task can be long and laborious.

Programs written using the MQAI pass parameters into the appropriate data bag, and you need only one statement for each structure. The use of the MQAI data bags removes the need for you to handle arrays and allocate storage, and provides some degree of isolation from the details of the PCF.

Handle error conditions more easily
It is difficult to get return codes back from PCF commands. The MQAI makes it easier for the program to handle error conditions.

After you have created and populated your data bag, you can send an administration command message to the command server of a queue manager, using the **mqExecute** call. This call waits for any response messages. The **mqExecute** call handles the exchange with the command server, and returns responses in a *response bag*.

For more information about the MQAI, see "Introduction to the IBM MQ Administration Interface (MQAI)."

Introduction to the IBM MQ Administration Interface (MQAI)

IBM MQ Administration Interface (MQAI) is a programming interface to IBM MQ. It performs administration tasks on an IBM MQ queue manager using data bags to handle properties (or parameters) of objects in a way that is easier than using Programmable Command Formats (PCFs).

MQAI concepts and terminology

The MQAI is a programming interface to IBM MQ, using the C language and also Visual Basic for Windows. It is available on platforms other than z/OS.

It performs administration tasks on an IBM MQ queue manager using data bags. Data bags allow you to handle properties (or parameters) of objects in a way that is easier than using the other administration interface, Programmable Command Formats (PCFs). The MQAI offers easier manipulation of PCFs than using the MQGET and MQPUT calls.

For more information about data bags, see "Data bags" on page 46. For more information about PCFs, see "Introduction to Programmable Command Formats" on page 6

Use of the MQAI

You can use the MQAI to:

- Simplify the use of PCF messages. The MQAI is an easy way to administer IBM MQ; you do not have to write your own PCF messages and thus avoid the problems associated with complex data structures.
- Handle error conditions more easily. It is difficult to get return codes back from the IBM MQ script (MQSC) commands, but the MQAI makes it easier for the program to handle error conditions.
- Exchange data between applications. The application data is sent in PCF format and packed and unpacked by the MQAI. If your message data consists of integers and character strings, you can use the MQAI to take advantage of IBM MQ built-in data conversion for PCF data. This avoids the need to write data-conversion exits. For more information on using MQAI to administer IBM MQ and to exchange data between applications, see "Using the MQAI to simplify the use of PCFs" on page 18.

Examples of using the MQAI

The list shown gives some example programs that demonstrate the use of MQAI. The samples perform the following tasks:

1. Create a local queue. "Creating a local queue (amqsaicq.c)" on page 20

2. Display events on the screen using a simple event monitor. “Displaying events using an event monitor (amqsaiem.c)” on page 25
3. Print a list of all local queues and their current depths. “Inquiring about queues and printing information (amqsailq.c)” on page 39
4. Print a list of all channels and their types. “Inquire channel objects (amqsaicl.c)” on page 33

Building your MQAI application

To build your application using the MQAI, you link to the same libraries as you do for IBM MQ. For information on how to build your IBM MQ applications, see Building a procedural application.

Hints and tips for configuring IBM MQ using MQAI

The MQAI uses PCF messages to send administration commands to the command server rather than dealing directly with the command server itself. Tips for configuring IBM MQ using the MQAI can be found in “Hints and tips for configuring IBM MQ” on page 44

IBM MQ Administration Interface (MQAI)

IBM MQ for Windows, AIX, IBM i IBM i, Linux, HP-UX, and Solaris support the IBM MQ Administration Interface (MQAI). The MQAI is a programming interface to IBM MQ that gives you an alternative to the MQI, for sending and receiving PCFs.

The MQAI uses *data bags* which allow you to handle properties (or parameters) of objects more easily than using PCFs directly by way of the MQAI.

The MQAI provides easier programming access to PCF messages by passing parameters into the data bag, so that only one statement is required for each structure. This access removes the need for the programmer to handle arrays and allocate storage, and provides some isolation from the details of PCF.

The MQAI administers IBM MQ by sending PCF messages to the command server and waiting for a response.

The MQAI is described in the second section of this manual. See the Using Java™ documentation for a description of a component object model interface to the MQAI.

Creating a local queue (amqsaicq.c)

```
/******************************************************************************/
/*                                                                            */
/* Program name: AMQSAICQ.C                                                   */

Hints and tips for configuring IBM MQ

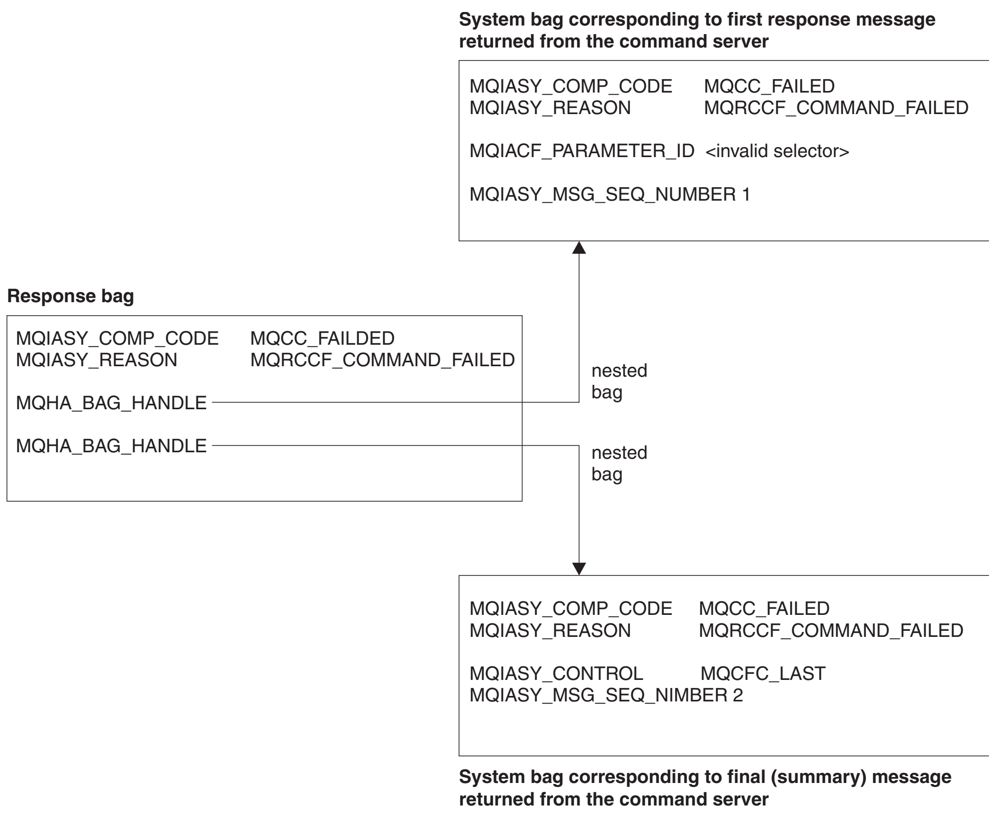
Programming hints and tips when using MQAI.

The MQAI uses PCF messages to send administration commands to the command server rather than dealing directly with the command server itself. Here are some tips for configuring IBM MQ using the MQAI:

- Character strings in IBM MQ are blank padded to a fixed length. Using C, null-terminated strings can normally be supplied as input parameters to IBM MQ programming interfaces.
- To clear the value of a string attribute, set it to a single blank rather than an empty string.
- Consider in advance the attributes that you want to change and inquire on just those attributes.
- Certain attributes cannot be changed, for example a queue name or a channel type. Ensure that you attempt to change only those attributes that can be modified. Refer to the list of required and optional parameters for the specific PCF change object. See Definitions of the Programmable Command Formats.
- If an MQAI call fails, some detail of the failure is returned to the response bag. Further detail can then be found in a nested bag that can be accessed by the selector MQHA_BAG_HANDLE. For example, if an mqExecute call fails with a reason code of MQRCCF_COMMAND_FAILED, this information is returned in the response bag. A possible reason for this reason code is that a selector specified was not valid for the type of command message and this detail of information is found in a nested bag that can be accessed by a bag handle.

  For more information on MQExecute, see "Sending administration commands to the command server using the mqExecute call" on page 54

  The following diagram shows this scenario:



System bag corresponding to first response message returned from the command server

MQIASY_CONTROL MQCFC_LAST
MQIASY_MSG_SEQ_NIMBER 2
System bag corresponding to final (summary) message returned from the command server

Advanced topics

Information on indexing, data conversion and use of message descriptor

- Indexing

  Indexes are used when replacing or removing existing data items from a bag to preserve insertion order. Full details on indexing can be found in Indexing.
- Data conversion

  The strings contained in an MQAI data bag can be in a variety of coded character sets and these can be converted using the mqSetInteger call. Full details on data conversion can be found in Data conversion.
- Use of the message descriptor

  MQAI generates a message descriptor which is set to an initial value when the data bag is created. Full details of the use of the message descriptor can be found in Use of the message descriptor.

Data bags

A data bag is a means of handling properties or parameters of objects using the MQAI.

Data Bags

- The data bag contains zero or more *data items*. These data items are ordered within the bag as they are placed into the bag. This is called the *insertion order*. Each data item contains a *selector* that identifies the data item and a *value* of that data item that can be either an integer, a 64-bit integer, an integer filter, a string, a string filter, a byte string, a byte string filter, or a handle of another bag. Data items are described in details in "Data item" on page 48

  There are two types of selector; *user selectors* and *system selectors*. These are described in MQAI Selectors. The selectors are usually unique, but it is possible to have multiple values for the same selector. In this case, an *index* identifies the particular occurrence of selector that is required. Indexes are described in Indexing.

  A hierarchy of these concepts is shown in Figure 1.

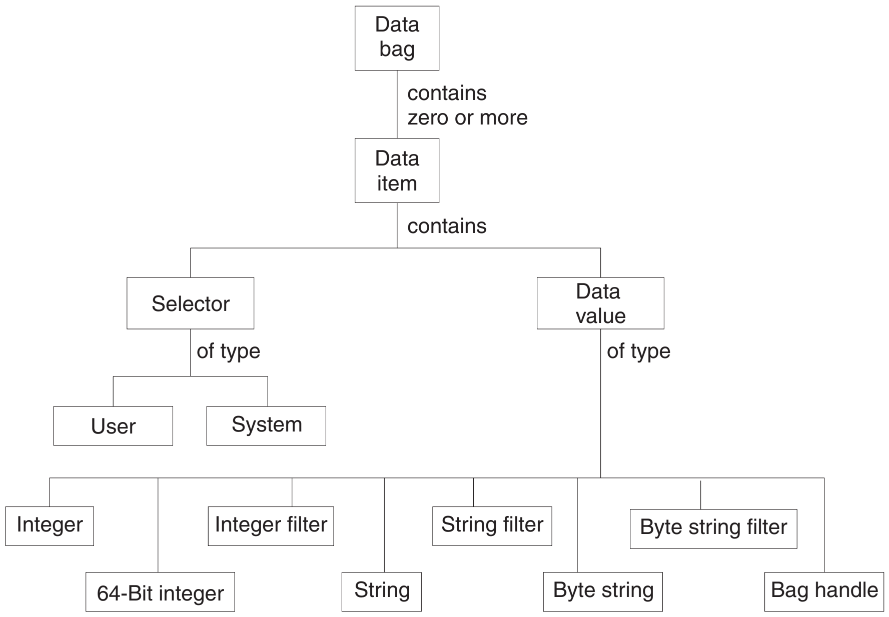

Figure 1. Hierarchy of MQAI concepts

The hierarchy has been explained in a previous paragraph.

Types of data bag

You can choose the type of data bag that you want to create depending on the task that you wish to perform:

user bag
A simple bag used for user data.

administration bag
A bag created for data used to administer IBM MQ objects by sending administration messages to a command server. The administration bag automatically implies certain options as described in "Creating and deleting data bags" on page 47.

command bag
A bag also created for commands for administering IBM MQ objects. However, unlike the

administration bag, the command bag does not automatically imply certain options although these options are available. For more information about options, see "Creating and deleting data bags."

group bag
A bag used to hold a set of grouped data items. Group bags cannot be used for administering IBM MQ objects.

In addition, the **system bag** is created by the MQAI when a reply message is returned from the command server and placed into a user's output bag. A system bag cannot be modified by the user.

Using Data Bags The different ways of using data bags are listed in this topic:

Using Data Bags

The different ways of using data bags are shown in the following list:
- You can create and delete data bags "Creating and deleting data bags."
- You can send data between applications using data bags "Putting and receiving data bags" on page 48.
- You can add data items to data bags "Adding data items to bags" on page 49.
- You can add an inquiry command within a data bag "Adding an inquiry command to a bag" on page 50.
- You can inquire within data bags "Inquiring within data bags" on page 51.
- You can count data items within a data bag "Counting data items" on page 53.
- You can change information within a data bag "Changing information within a bag" on page 51.
- You can clear a data bag "Clearing a bag using the mqClearBag call" on page 52.
- You can truncate a data bag "Truncating a bag using the mqTruncateBag call" on page 52.
- You can convert bags and buffers "Converting bags and buffers" on page 53.

Creating and deleting data bags:

Creating data bags

To use the MQAI, you first create a data bag using the mqCreateBag call. As input to this call, you supply one or more options to control the creation of the bag.

The `Options` parameter of the MQCreateBag call lets you choose whether to create a user bag, a command bag, a group bag, or an administration bag.

To create a user bag, a command bag, or a group bag, you can choose one or more further options to:
- Use the list form when there are two or more adjacent occurrences of the same selector in a bag.
- Reorder the data items as they are added to a PCF message to ensure that the parameters are in their correct order. For more information on data items, see "Data item" on page 48.
- Check the values of user selectors for items that you add to the bag.

Administration bags automatically imply these options.

A data bag is identified by its handle. The bag handle is returned from mqCreateBag and must be supplied on all other calls that use the data bag.

For a full description of the mqCreateBag call, see mqCreateBag.

Deleting data bags

Any data bag that is created by the user must also be deleted using the mqDeleteBag call. For example, if a bag is created in the user code, it must also be deleted in the user code.

System bags are created and deleted automatically by the MQAI. For more information about this, see "Sending administration commands to the command server using the mqExecute call" on page 54. User code cannot delete a system bag.

For a full description of the mqDeleteBag call, see mqDeleteBag.

Putting and receiving data bags:

Data can also be sent between applications by putting and getting data bags using the mqPutBag and mqGetBag calls. This lets the MQAI handle the buffer rather than the application. The mqPutBag call converts the contents of the specified bag into a PCF message and sends the message to the specified queue and the mqGetBag call removes the message from the specified queue and converts it back into a data bag. Therefore, the mqPutBag call is the equivalent of the mqBagToBuffer call followed by MQPUT, and the mqGetBag is the equivalent of the MQGET call followed by mqBufferToBag.

For more information on sending and receiving PCF messages in a specific queue, see "Sending and receiving PCF messages in a specified queue" on page 9

Note: If you choose to use the mqGetBag call, the PCF details within the message must be correct; if they are not, an appropriate error results and the PCF message is not returned.

Data item:

Data items are used to populate data bags when they are created. These data items can be user or system items.

These user items contain user data such as attributes of objects that are being administered. System items should be used for more control over the messages generated: for example, the generation of message headers. For more information about system items, see "System items" on page 49.

Types of Data Items

When you have created a data bag, you can populate it with integer or character-string items. You can inquire about all three types of item.

The data item can either be integer or character-string items. Here are the types of data item available within the MQAI:
- Integer
- 64-bit integer
- Integer filter
- Character-string
- String filter
- Byte string
- Byte string filter
- Bag handle

Using Data Items

These are the following ways of using data items:
- "Counting data items" on page 53.
- "Deleting data items" on page 53.
- "Adding data items to bags."
- "Filtering and querying data items" on page 50.

System items:

System items can be used for:
- The generation of PCF headers. System items can control the PCF command identifier, control options, message sequence number, and command type.
- Data conversion. System items handle the character-set identifier for the character-string items in the bag.

Like all data items, system items consist of a selector and a value. For information about these selectors and what they are for, see MQAI Selectors.

System items are unique. One or more system items can be identified by a system selector. There is only one occurrence of each system selector.

Most system items can be modified (see "Changing information within a bag" on page 51), but the bag-creation options cannot be changed by the user. You cannot delete system items. (See "Deleting data items" on page 53.)

Adding data items to bags:

When a data bag is created, you can populate it with data items. These data items can be user or system items. For more information about data items, see "Data item" on page 48.

The MQAI lets you add integer items, 64-bit integer items, integer filter items, character-string items, string filter, byte string items, and byte string filter items to bags and this is shown in Figure 2. The items are identified by a selector. Usually one selector identifies one item only, but this is not always the case. If a data item with the specified selector is already present in the bag, an additional instance of that selector is added to the end of the bag.

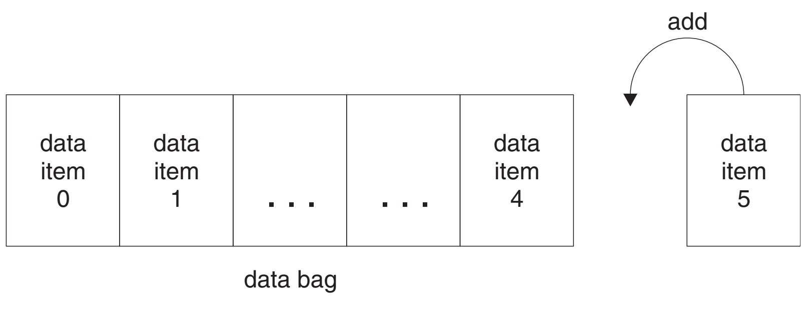

Figure 2. Adding data items

Add data items to a bag using the mqAdd* calls:
- To add integer items, use the mqAddInteger call as described in mqAddInteger
- To add 64-bit integer items, use the mqAddInteger64 call as described in mqAddInteger64
- To add integer filter items, use the mqAddIntegerFilter call as described in mqAddIntegerFilter
- To add character-string items, use the mqAddString call as described in mqAddString

- To add string filter items, use the mqAddStringFilter call as described in mqAddStringFilter
- To add byte string items, use the mqAddByteString call as described in mqAddByteString
- To add byte string filter items, use the mqAddByteStringFilter call as described in mqAddByteStringFilter

For more information on adding data items to a bag, see "System items" on page 49.

Adding an inquiry command to a bag:

The mqAddInquiry call is used to add an inquiry command to a bag. The call is specifically for administration purposes, so it can be used with administration bags only. It lets you specify the selectors of attributes on which you want to inquire from IBM MQ.

For a full description of the mqAddInquiry call, see mqAddInquiry.

Filtering and querying data items:

When using the MQAI to inquire about the attributes of IBM MQ objects, you can control the data that is returned to your program in two ways.

- You can ***filter*** the data that is returned using the mqAddInteger and mqAddString calls. This approach lets you specify a *Selector* and *ItemValue* pair, for example:
  ```
  mqAddInteger(inputbag, MQIA_Q_TYPE, MQQT_LOCAL)
  ```
  This example specifies that the queue type (*Selector*) must be local (*ItemValue*) and this specification must match the attributes of the object (in this case, a queue) about which you are inquiring.

  Other attributes that can be filtered correspond to the PCF Inquire* commands that can be found in "Introduction to Programmable Command Formats" on page 6. For example, to inquire about the attributes of a channel, see the Inquire Channel command in this product documentation. The "Required parameters" and "Optional parameters" of the Inquire Channel command identify the selectors that you can use for filtering.
- You can ***query*** particular attributes of an object using the mqAddInquiry call. This specifies the selector in which you are interested. If you do not specify the selector, all attributes of the object are returned.

Here is an example of filtering and querying the attributes of a queue:

```
/* Request information about all queues */
mqAddString(adminbag, MQCA_Q_NAME, "*")

/* Filter attributes so that local queues only are returned */
mqAddInteger(adminbag, MQIA_Q_TYPE, MQQT_LOCAL)

/* Query the names and current depths of the local queues */
mqAddInquiry(adminbag, MQCA_Q_NAME)
mqAddInquiry(adminbag, MQIA_CURRENT_Q_DEPTH)

/* Send inquiry to the command server and wait for reply */
mqExecute(MQCMD_INQUIRE_Q, ...)
```

For more examples of filtering and querying data items, see "Examples of using the MQAI" on page 19.

Inquiring within data bags:

You can inquire about:
- The value of an integer item using the mqInquireInteger call. See mqInquireInteger.
- The value of a 64-bit integer item using the mqInquireInteger64 call. See mqInquireInteger64.
- The value of an integer filter item using the mqInquireIntegerFilter call. See mqInquireIntegerFilter.
- The value of a character-string item using the mqInquireString call. See mqInquireString.
- The value of a string filter item using the mqInquireStringFilter call. See mqInquireStringFilter.
- The value of a byte string item using the mqInquireByteString call. See mqInquireByteString.
- The value of a byte string filter item using the mqInquireByteStringFilter call. See mqInquireByteStringFilter.
- The value of a bag handle using the mqInquireBag call. See mqInquireBag.

You can also inquire about the type (integer, 64-bit integer, integer filter, character string, string filter, byte string, byte string filter or bag handle) of a specific item using the mqInquireItemInfo call. See mqInquireItemInfo.

Changing information within a bag:

The MQAI lets you change information within a bag using the mqSet* calls. You can:
1. Modify data items within a bag. The index allows an individual instance of a parameter to be replaced by identifying the occurrence of the item to be modified (see Figure 3).

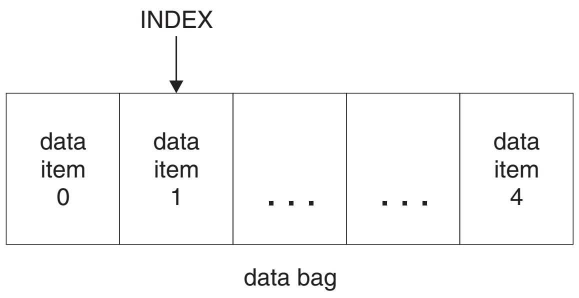

Figure 3. Modifying a single data item

2. Delete all existing occurrences of the specified selector and add a new occurrence to the end of the bag. (See Figure 4.) A special index value allows ***all*** instances of a parameter to be replaced.

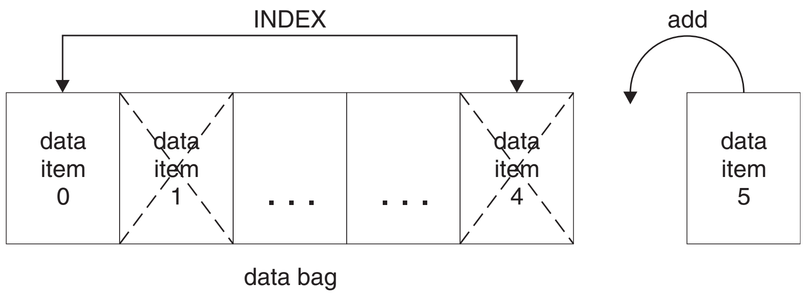

Figure 4. Modifying all data items

Note: The index preserves the insertion order within the bag but can affect the indices of other data items.

The mqSetInteger call lets you modify integer items within a bag. The mqSetInteger64 call lets you modify 64-bit integer items. The mqSetIntegerFilter call lets you modify integer filter items. The mqSetString call lets you modify character-string items. The mqSetStringFilter call lets you modify string filter items. The mqSetByteString call lets you modify byte string items. The mqSetByteStringFilter call lets you modify byte string filter items. Alternatively, you can use these calls to delete all existing occurrences of the specified selector and add a new occurrence at the end of the bag. The data item can be a user item or a system item.

For a full description of these calls, see:
- mqSetInteger
- mqSetInteger64
- mqSetIntegerFilter
- mqSetString
- mqSetStringFilter
- mqSetByteString
- mqSetByteStringFilter

Clearing a bag using the mqClearBag call:

The mqClearBag call removes all user items from a user bag and resets system items to their initial values. System bags contained within the bag are also deleted.

For a full description of the mqClearBag call, see mqClearBag.

Truncating a bag using the mqTruncateBag call:

The mqTruncateBag call reduces the number of user items in a user bag by deleting the items from the end of the bag, starting with the most recently added item. For example, it can be used when using the same header information to generate more than one message.

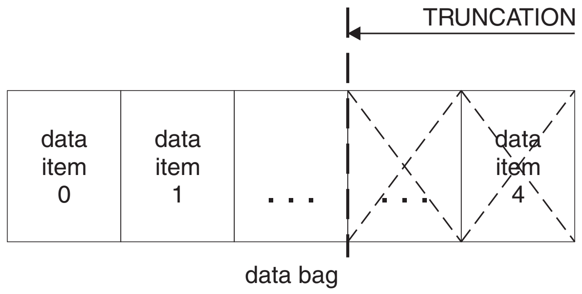

Figure 5. Truncating a bag

For a full description of the mqTruncateBag call, see mqTruncateBag.

Converting bags and buffers:

To send data between applications, firstly the message data is placed in a bag. Then, the data in the bag is converted into a PCF message using the mqBagToBuffer call. The PCF message is sent to the required queue using the MQPUT call. This is shown in Figure Figure 6. For a full description of the mqBagToBuffer call, see mqBagToBuffer.

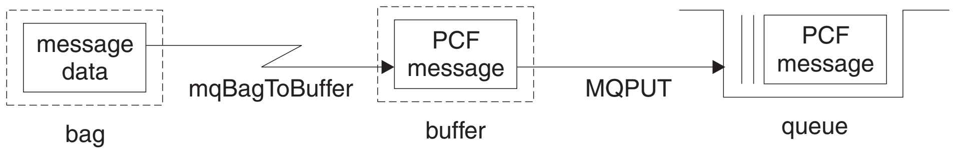

Figure 6. Converting bags to PCF messages

To receive data, the message is received into a buffer using the MQGET call. The data in the buffer is then converted into a bag using the mqBufferToBag call, providing the buffer contains a valid PCF message. This is shown in Figure Figure 7. For a full description of the mqBufferToBag call, see mqBufferToBag.

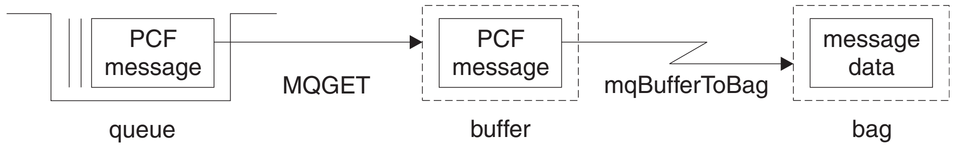

Figure 7. Converting PCF messages to bag form

Counting data items: The mqCountItems call counts the number of user items, system items, or both, that are stored in a data bag, and returns this number. For example, `mqCountItems( Bag, 7, ...)`, returns the number of items in the bag with a selector of 7. It can count items by individual selector, by user selectors, by system selectors, or by all selectors.

Note: This call counts the number of data items, not the number of unique selectors in the bag. A selector can occur multiple times, so there might be fewer unique selectors in the bag than data items.

For a full description of the mqCountItems call, see mqCountItems.

Deleting data items:

You can delete items from bags in a number of ways. You can:
- Remove one or more user items from a bag. For detailed information, see “Deleting data items from a bag using the mqDeleteItem call” on page 54.
- Delete ***all*** user items from a bag, that is, *clear* a bag. For detailed information see “Clearing a bag using the mqClearBag call” on page 52.
- Delete user items from the end of a bag, that is, *truncate* a bag. For detailed information, see “Truncating a bag using the mqTruncateBag call” on page 52.

Deleting data items from a bag using the mqDeleteItem call:

The mqDeleteItem call removes one or more user items from a bag. The index is used to delete either:

1. A single occurrence of the specified selector. (See Figure 8.)

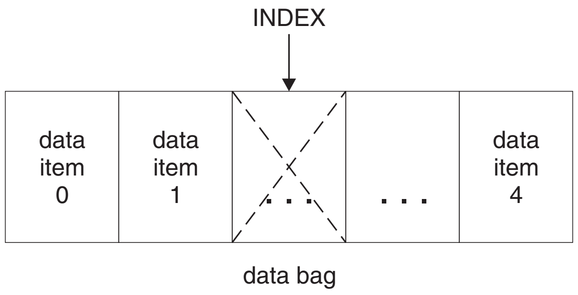

Figure 8. Deleting a single data item

or

2. All occurrences of the specified selector. (See Figure 9.)

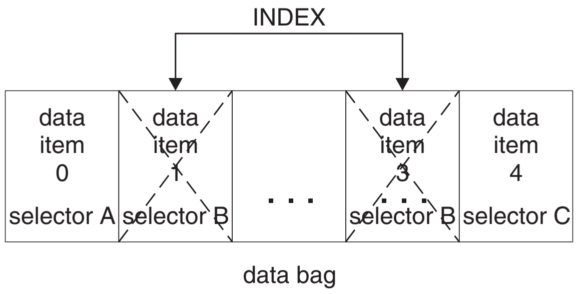

Figure 9. Deleting all data items

Note: The index preserves the insertion order within the bag but can affect the indices of other data items. For example, the mqDeleteItem call does not preserve the index values of the data items that follow the deleted item because the indices are reorganized to fill the gap that remains from the deleted item.

For a full description of the mqDeleteItem call, see mqDeleteItem.

Sending administration commands to the command server using the mqExecute call

When a data bag has been created and populated, an administrative command message can be sent to the command server of a queue manager using the mqExecute call. This handles the exchange with the command server and returns responses in a bag.

After you have created and populated your data bag, you can send an administration command message to the command server of a queue manager. The easiest way to do this is by using the mqExecute call. The mqExecute call sends an administration command message as a nonpersistent message and waits for any responses. Responses are returned in a response bag. These might contain information about attributes relating to several IBM MQ objects or a series of PCF error response messages, for example. Therefore, the response bag could contain a return code only or it could contain *nested bags*.

Response messages are placed into system bags that are created by the system. For example, for inquiries about the names of objects, a system bag is created to hold those object names and the bag is inserted into the user bag. Handles to these bags are then inserted into the response bag and the nested bag can be accessed by the selector MQHA_BAG_HANDLE. The system bag stays in storage, if it is not deleted, until the response bag is deleted.

The concept of *nesting* is shown in Figure 10.

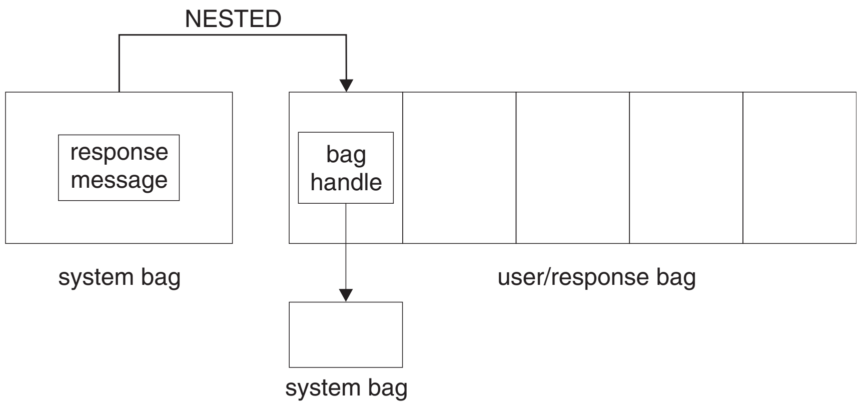

Figure 10. Nesting

As input to the mqExecute call, you must supply:
- An MQI connection handle.
- The command to be executed. This should be one of the MQCMD_* values.

  Note: If this value is not recognized by the MQAI, the value is still accepted. However, if the mqAddInquiry call was used to insert values into the bag, this parameter must be an INQUIRE command recognized by the MQAI. That is, the parameter should be of the form MQCMD_INQUIRE_*.
- Optionally, a handle of the bag containing options that control the processing of the call. This is also where you can specify the maximum time in milliseconds that the MQAI should wait for each reply message.
- A handle of the administration bag that contains details of the administration command to be issued.
- A handle of the response bag that receives the reply messages.

The following are optional:
- An object handle of the queue where the administration command is to be placed.

  If no object handle is specified, the administration command is placed on the SYSTEM.ADMIN.COMMAND.QUEUE belonging to the currently connected queue manager. This is the default.
- An object handle of the queue where reply messages are to be placed.

  You can choose to place the reply messages on a dynamic queue that is created automatically by the MQAI. The queue created exists for the duration of the call only, and is deleted by the MQAI on exit from the mqExecute call.

For examples uses of the mqExecute call, see Example code

Administration using the MQ Explorer

The MQ Explorer allows you to perform local or remote administration of your network from a computer running Windows, or Linux x86-64 only.

IBM MQ for Windows and IBM MQ for Linux x86-64 provide an administration interface called the MQ Explorer to perform administration tasks as an alternative to using control or MQSC commands. Comparing command sets shows you what you can do using the MQ Explorer.

The MQ Explorer allows you to perform local or remote administration of your network from a computer running Windows, or Linux x86-64, by pointing the MQ Explorer at the queue managers and clusters you are interested in. The platforms and levels of IBM MQ that can be administered using the MQ Explorer are described in "Remote queue managers" on page 57.

To configure remote IBM MQ queue managers so that MQ Explorer can administer them, see "Prerequisite software and definitions" on page 58.

It allows you to perform tasks, typically associated with setting up and fine-tuning the working environment for IBM MQ, either locally or remotely within a Windows or Linux x86-64 system domain.

On Linux, the MQ Explorer might fail to start if you have more than one Eclipse installation. If this happens, start the MQ Explorer using a different user ID to the one you use for the other Eclipse installation.

On Linux, to start the MQ Explorer successfully, you must be able to write a file to your home directory, and the home directory must exist.

What you can do with the IBM MQ Explorer

This is a list of the tasks that you can perform using the IBM MQ Explorer.

With the IBM MQ Explorer, you can:

- Create and delete a queue manager (on your local machine only).
- Start and stop a queue manager (on your local machine only).
- Define, display, and alter the definitions of IBM MQ objects such as queues and channels.
- Browse the messages on a queue.
- Start and stop a channel.
- View status information about a channel, listener, queue, or service objects.
- View queue managers in a cluster.
- Check to see which applications, users, or channels have a particular queue open.
- Create a new queue manager cluster using the *Create New Cluster* wizard.
- Add a queue manager to a cluster using the *Add Queue Manager to Cluster* wizard.
- Manage the authentication information object, used with Secure Sockets Layer (SSL) channel security.
- Create and delete channel initiators, trigger monitors, and listeners.
- Start or stop the command servers, channel initiators, trigger monitors, and listeners.
- Set specific services to start automatically when a queue manager is started.
- Modify the properties of queue managers.
- Change the local default queue manager.
- Invoke the ikeyman GUI to manage secure sockets layer (SSL) certificates, associate certificates with queue managers, and configure and setup certificate stores (on your local machine only).
- Create JMS objects from IBM MQ objects, and IBM MQ objects from JMS objects.
- Create a JMS Connection Factory for any of the currently supported types.

- Modify the parameters for any service, such as the TCP port number for a listener, or a channel initiator queue name.
- Start or stop the service trace.

You perform administration tasks using a series of *Content Views* and *Property dialogs*.

Content View
A Content View is a panel that can display the following:
- Attributes, and administrative options relating to IBM MQ itself.
- Attributes, and administrative options relating to one or more related objects.
- Attributes, and administrative options for a cluster.

Property dialogs
A property dialog is a panel that displays attributes relating to an object in a series of fields, some of which you can edit.

You navigate through the IBM MQ Explorer using the *Navigator view*. The Navigator allows you to select the Content View you require.

Remote queue managers

There are two exceptions to the supported queue managers that you can connect to.

From a Windows or Linux (x86 and x86-64 platforms) system, the IBM MQ Explorer can connect to all supported queue managers with the following exceptions:
- IBM MQ for z/OS queue managers earlier than Version 6.0.
- Currently supported MQSeries® V2 queue managers.

The IBM MQ Explorer handles the differences in the capabilities between the different command levels and platforms. However, if it encounters an attribute that it does not recognize, the attribute will not be visible.

If you intend to remotely administer a V6.0 or later queue manager on Windows using the IBM MQ Explorer on an IBM MQ V5.3 computer, you must install Fix Pack 9 (CSD9) or later on your IBM MQ for Windows V5.3 computer.

If you intend to remotely administer a V5.3 queue manager on iSeries using the IBM MQ Explorer on an IBM MQ V6.0 or later computer, you must install Fix Pack 11 (CSD11) or later on your IBM MQ for iSeries V5.3 computer. This fix pack corrects connection problems between the IBM MQ Explorer and the iSeries queue manager.

Deciding whether to use the IBM MQ Explorer

When deciding whether to use the IBM MQ Explorer at your installation, consider the information listed in this topic.

You need to be aware of the following points:

Object names
: If you use lowercase names for queue managers and other objects with the IBM MQ Explorer, when you work with the objects using MQSC commands, you must enclose the object names in single quotation marks, or IBM MQ does not recognize them.

Large queue managers
: The IBM MQ Explorer works best with small queue managers. If you have a large number of objects on a single queue manager, you might experience delays while the IBM MQ Explorer extracts the required information to present in a view.

Clusters
: IBM MQ clusters can potentially contain hundreds or thousands of queue managers. The IBM MQ Explorer presents the queue managers in a cluster using a tree structure. The physical size of a cluster does not affect the speed of the IBM MQ Explorer dramatically because the IBM MQ Explorer does not connect to the queue managers in the cluster until you select them.

Setting up the IBM MQ Explorer

This section outlines the steps you need to take to set up the IBM MQ Explorer.

- "Prerequisite software and definitions"
- "Security" on page 59
- "Showing and hiding queue managers and clusters" on page 62
- "Cluster membership" on page 63
- "Data conversion" on page 64

Prerequisite software and definitions

Ensure that you satisfy the following requirements before trying to use the MQ Explorer.

The MQ Explorer can connect to remote queue managers using the TCP/IP communication protocol only.

Check that:

1. A command server is running on every remotely administered queue manager.
2. A suitable TCP/IP listener object must be running on every remote queue manager. This object can be the IBM MQ listener or, on UNIX and Linux systems, the inetd daemon.
3. A server-connection channel, by default named SYSTEM.ADMIN.SVRCONN, exists on all remote queue managers.

   You can create the channel using the following MQSC command:

   ```
   DEFINE CHANNEL(SYSTEM.ADMIN.SVRCONN) CHLTYPE(SVRCONN)
   ```

   This command creates a basic channel definition. If you want a more sophisticated definition (to set up security, for example), you need additional parameters. For more information, see DEFINE CHANNEL.
4. The system queue, SYSTEM.MQEXPLORER.REPLY.MODEL, must exist.

Security

If you are using IBM MQ in an environment where it is important for you to control user access to particular objects, you might need to consider the security aspects of using the IBM MQ Explorer.

Authorization to use the IBM MQ Explorer:

Any user can use the IBM MQ Explorer, but certain authorities are required to connect, access, and manage queue managers.

To perform local administrative tasks using the IBM MQ Explorer, a user is required to have the necessary authority to perform the administrative tasks. If the user is a member of the mqm group, the user has authority to perform all local administrative tasks.

To connect to a remote queue manager and perform remote administrative tasks using the IBM MQ Explorer, the user executing the IBM MQ Explorer is required to have the following authorities:
- CONNECT authority on the target queue manager object
- INQUIRE authority on the target queue manager object
- DISPLAY authority to the target queue manager object
- INQUIRE authority to the queue, SYSTEM.MQEXPLORER.REPLY.MODEL
- DISPLAY authority to the queue, SYSTEM.MQEXPLORER.REPLY.MODEL
- INPUT (get) authority to the queue, SYSTEM.MQEXPLORER.REPLY.MODEL
- OUTPUT (put) authority to the queue, SYSTEM.ADMIN.COMMAND.QUEUE
- INQUIRE authority on the queue, SYSTEM.ADMIN.COMMAND.QUEUE
- Authority to perform the action selected

Note: INPUT authority relates to input to the user from a queue (a get operation). OUTPUT authority relates to output from the user to a queue (a put operation).

To connect to a remote queue manager on IBM MQ for z/OS and perform remote administrative tasks using the IBM MQ Explorer, the following must be provided:
- A RACF® profile for the system queue, SYSTEM.MQEXPLORER.REPLY.MODEL
- A RACF profile for the queues, AMQ.MQEXPLORER.*

In addition, the user executing the IBM MQ Explorer is required to have the following authorities:
- RACF UPDATE authority to the system queue, SYSTEM.MQEXPLORER.REPLY.MODEL
- RACF UPDATE authority to the queues, AMQ.MQEXPLORER.*
- CONNECT authority on the target queue manager object
- Authority to perform the action selected
- READ authority to all the hlq.DISPLAY.object profiles in the MQCMDS class

For information about how to grant authority to IBM MQ objects, see Giving access to an IBM MQ object on UNIX or Linux systems and Windows .

If a user attempts to perform an operation that they are not authorized to perform, the target queue manager invokes authorization failure procedures and the operation fails.

The default filter in the IBM MQ Explorer is to display all IBM MQ objects. If there are any IBM MQ objects that a user does not have DISPLAY authority to, authorization failures are generated. If authority events are being recorded, restrict the range of objects that are displayed to those objects that the user has DISPLAY authority to.

Security for connecting to remote queue managers:

You must secure the channel between the IBM MQ Explorer and each remote queue manager.

The IBM MQ Explorer connects to remote queue managers as an MQI client application. This means that each remote queue manager must have a definition of a server-connection channel and a suitable TCP/IP listener. If you do not secure your server connection channel it is possible for a malicious application to connect to the same server connection channel and gain access to the queue manager objects with unlimited authority. In order to secure your server connection channel either specify a non-blank value for the MCAUSER attribute of the channel, use channel authentication records, or use a security exit.

The default value of the MCAUSER attribute is the local user ID. If you specify a non-blank user name as the MCAUSER attribute of the server connection channel, all programs connecting to the queue manager using this channel run with the identity of the named user and have the same level of authority. This does not happen if you use channel authentication records.

Using a security exit with the IBM MQ Explorer:

You can specify a default security exit and queue manager specific security exits using the IBM MQ Explorer.

You can define a default security exit, which can be used for all new client connections from the IBM MQ Explorer. This default exit can be overridden at the time a connection is made. You can also define a security exit for a single queue manager or a set of queue managers, which takes effect when a connection is made. You specify exits using the IBM MQ Explorer. For more information, see the IBM MQ Help Center.

Using the MQ Explorer to connect to a remote queue manager using SSL-enabled MQI channels:

The MQ Explorer connects to remote queue managers using an MQI channel. If you want to secure the MQI channel using SSL security, you must establish the channel using a client channel definition table.

For information how to establish an MQI channel using a client channel definition table, see Overview of IBM MQ MQI clients.

When you have established the channel using a client channel definition table, you can use the MQ Explorer to connect to a remote queue manager using SSL-enabled MQI channel, as described in "Tasks on the system that hosts the remote queue manager" and "Tasks on the system that hosts the MQ Explorer" on page 61.

Tasks on the system that hosts the remote queue manager

On the system hosting the remote queue manager, perform the following tasks:

1. Define a server connection and client connection pair of channels, and specify the appropriate value for the *SSLCIPH* variable on the server connection on both channels. For more information about the *SSLCIPH* variable, see Protecting channels with SSL
2. Send the channel definition table `AMQCLCHL.TAB`, which is found in the queue manager's `@ipcc` directory, to the system hosting the MQ Explorer.
3. Start a TCP/IP listener on a designated port.
4. Place both the CA and personal SSL certificates into the SSL directory of the queue manager:
   - `/var/mqm/qmgrs/+QMNAME+/SSL` for UNIX and Linux systems
   - `C:\Program Files\IBM\WebSphere MQ\qmgrs\+QMNAME+\SSL` for Windows systems

   Where `+QMNAME+` is a token representing the name of the queue manager.

5. Create a key database file of type CMS named `key.kdb`. Stash the password in a file either by checking the option in the iKeyman GUI, or by using the `-stash` option with the **`runmqckm`** commands.
6. Add the CA certificates to the key database created in the previous step.
7. Import the personal certificate for the queue manager into the key database.

For more detailed information about working with the Secure Sockets Layer on Windows systems, see Working with SSL or TLS on UNIX, Linux and Windows systems.

Tasks on the system that hosts the MQ Explorer

On the system hosting the MQ Explorer, perform the following tasks:

1. Create a key database file of type JKS named `key.jks`. Set a password for this key database file.

   The MQ Explorer uses Java keystore files (JKS) for SSL security, and so the keystore file being created for configuring SSL for the MQ Explorer must match this.
2. Add the CA certificates to the key database created in the previous step.
3. Import the personal certificate for the queue manager into the key database.
4. On Windows and Linux systems, start MQ Explorer by using the system menu, the `MQExplorer` executable file, or the **`strmqcfg`** command.
5. From the MQ Explorer toolbar, click **Window -> Preferences**, then expand **IBM MQ Explorer** and click **SSL Client Certificate Stores**. Enter the name of, and password for, the JKS file created in step 1 of "Tasks on the system that hosts the MQ Explorer," in both the Trusted Certificate Store and the Personal Certificate Store, then click **OK**.
6. Close the **Preferences** window, and right-click **Queue Managers**. Click **Show/Hide Queue Managers**, and then click **Add** on the **Show/Hide Queue Managers** screen.
7. Type the name of the queue manager, and select the **Connect directly** option. Click next.
8. Select **Use client channel definition table (CCDT)** and specify the location of the channel table file that you transferred from the remote queue manager in step 2 in "Tasks on the system that hosts the remote queue manager" on page 60 on the system hosting the remote queue manager.
9. Click **Finish**. You can now access the remote queue manager from the MQ Explorer.

Connecting through another queue manager:

The IBM MQ Explorer allows you to connect to a queue manager through an intermediate queue manager, to which the IBM MQ Explorer is already connected.

In this case, the IBM MQ Explorer puts PCF command messages to the intermediate queue manager, specifying the following:

- The *ObjectQMgrName* parameter in the object descriptor (MQOD) as the name of the target queue manager. For more information on queue name resolution, see the Name resolution.
- The *UserIdentifier* parameter in the message descriptor (MQMD) as the local userId.

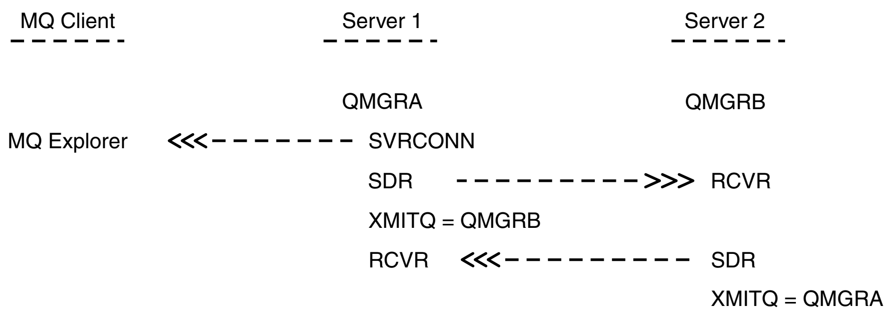
If the connection is then used to connect to the target queue manager via an intermediate queue manager, the userId is flowed in the *UserIdentifier* parameter of the message descriptor (MQMD) again. In order for the MCA listener on the target queue manager to accept this message, either the MCAUSER attribute must be set, or the userId must already exist with put authority.

The command server on the target queue manager puts messages to the transmission queue specifying the userId in the *UserIdentifier* parameter in the message descriptor (MQMD). For this put to succeed the userId must already exist on the target queue manager with put authority.

The following example shows you how to connect a queue manager, through an intermediate queue manager, to the IBM MQ Explorer.

Establish a remote administration connection to a queue manager. Verify that the:

- Queue manager on the server is active and has a server-connection channel (SVRCONN) defined.
- Listener is active.
- Command server is active.
- SYSTEM.MQ EXPLORER.REPLY.MODEL queue has been created and that you have sufficient authority.
- Queue manager listeners, command servers, and sender channels are started.



In this example:

- IBM MQ Explorer is connected to queue manager QMGRA (running on Server1) using a client connection.
- Queue manager QMGRB on Server2 can be now connected to IBM MQ Explorer through an intermediate queue manager (QMGRA)
- When connecting to QMGRB with IBM MQ Explorer, select QMGRA as the intermediate queue manager

In this situation, there is no direct connection to QMGRB from IBM MQ Explorer; the connection to QMGRB is through QMGRA.

Queue manager QMGRB on Server2 is connected to QMGRA on Server1 using sender-receiver channels. The channel between QMGRA and QMGRB must be set up in such a way that remote administration is possible; see "Preparing channels and transmission queues for remote administration" on page 133.

Showing and hiding queue managers and clusters

The IBM MQ Explorer can display more than one queue manager at a time. From the Show/Hide Queue Manager panel (selectable from the menu for the Queue Managers tree node), you can choose whether you display information about another (remote) machine. Local queue managers are detected automatically.

To show a remote queue manager:

1. Right-click the **Queue Managers** tree node, then select *Show/Hide Queue Managers...*.
2. Click **Add**. The Show/Hide Queue Managers panel is displayed.
3. Enter the name of the remote queue manager and the host name or IP address in the fields provided.

   The host name or IP address is used to establish a client connection to the remote queue manager using either its default server connection channel, SYSTEM.ADMIN.SVRCONN, or a user-defined server connection channel.
4. Click **Finish**.

The Show/Hide Queue Managers panel also displays a list of all visible queue managers. You can use this panel to hide queue managers from the navigation view.

If the IBM MQ Explorer displays a queue manager that is a member of a cluster, the cluster is detected, and displayed automatically.

To export the list of remote queue managers from this panel:
1. Close the Show/Hide Queue Managers panel.
2. Right-click the top **IBM MQ** tree node in the Navigation pane of the IBM MQ Explorer, then select **Export MQ Explorer Settings**
3. Click **MQ Explorer > MQ Explorer Settings**
4. Select **Connection Information > Remote queue managers**.
5. Select a file to store the exported settings in.
6. Finally, click **Finish** to export the remote queue manager connection information to the specified file.

To import a list of remote queue managers:
1. Right-click the top **IBM MQ** tree node in the Navigation pane of the IBM MQ Explorer, then select **Import MQ Explorer Settings**
2. Click **MQ Explorer > MQ Explorer Settings**
3. Click **Browse**, and navigate to the path of the file that contains the remote queue manager connection information.
4. Click **Open**. If the file contains a list of remote queue managers, the **Connection Information > Remote queue managers** box is selected.
5. Finally, click **Finish** to import the remote queue manager connection information into the IBM MQ Explorer.

Cluster membership

IBM MQ Explorer requires information about queue managers that are members of a cluster.

If a queue manager is a member of a cluster, then the cluster tree node will be populated automatically.

If queue managers become members of clusters while the IBM MQ Explorer is running, then you must maintain the IBM MQ Explorer with up-to-date administration data about clusters so that it can communicate effectively with them and display correct cluster information when requested. In order to do this, the IBM MQ Explorer needs the following information:
- The name of a repository queue manager
- The connection name of the repository queue manager if it is on a remote queue manager

With this information, the IBM MQ Explorer can:
- Use the repository queue manager to obtain a list of queue managers in the cluster.
- Administer the queue managers that are members of the cluster and are on supported platforms and command levels.

Administration is not possible if:
- The chosen repository becomes unavailable. The IBM MQ Explorer does not automatically switch to an alternative repository.
- The chosen repository cannot be contacted over TCP/IP.
- The chosen repository is running on a queue manager that is running on a platform and command level not supported by the IBM MQ Explorer.

The cluster members that can be administered can be local, or they can be remote if they can be contacted using TCP/IP. The IBM MQ Explorer connects to local queue managers that are members of a cluster directly, without using a client connection.

Data conversion

The IBM MQ Explorer works in CCSID 1208 (UTF-8). This enables the IBM MQ Explorer to display the data from remote queue managers correctly. Whether connecting to a queue manager directly, or by using an intermediate queue manager, the IBM MQ Explorer requires all incoming messages to be converted to CCSID 1208 (UTF-8).

An error message is issued if you try to establish a connection between the IBM MQ Explorer and a queue manager with a CCSID that the IBM MQ Explorer does not recognize.

Supported conversions are described in Code page conversion.

Security on Windows

The Prepare IBM MQ wizard creates a special user account so that the Windows service can be shared by processes that need to use it.

A Windows service is shared between client processes for an IBM MQ installation. One service is created for each installation. Each service is named `MQ_`*`InstallationName`*, and has a display name of `IBM MQ(`*`InstallationName`*`)`. Before Version 7.1, with only one installation on a server the single, Windows service was named MQSeriesServices with the display name `MQSeries`.

Because each service must be shared between non-interactive and interactive logon sessions, you must launch each under a special user account. You can use one special user account for all the services, or create different special user accounts. Each special user account must have the user right to "Logon as a service", for more information see "User rights required for an IBM MQ Windows Service" on page 65

When you install IBM MQ and run the Prepare IBM MQ wizard for the first time, it creates a local user account for the service called MUSR_MQADMIN with the required settings and permissions, including "Logon as a service".

For subsequent installations, the Prepare IBM MQ wizard creates a user account named MUSR_MQADMINx, where x is the next available number representing a user ID that does not exist. The password for MUSR_MQADMINx is randomly generated when the account is created, and used to configure the logon environment for the service. The generated password does not expire.

This IBM MQ account is not affected by any account policies that are set up on the system to require that account passwords are changed after a certain period.

The password is not known outside this one-time processing and is stored by the Windows operating system in a secure part of the registry.

Related information:

Windows: "Logon as a service" required

Using Active directory (Windows only)

In some network configurations, where user accounts are defined on domain controllers that are using Active Directory, the local user account IBM MQ is running under might not have the authority it requires to query the group membership of other domain user accounts. The Prepare IBM MQ Wizard identifies whether this is the case by carrying out tests and asking the user questions about the network configuration.

If the local user account IBM MQ is running under does not have the required authority, the Prepare IBM MQ Wizard prompts the user for the account details of a domain user account with particular user rights. For the user rights that the domain user account requires see "User rights required for an IBM MQ Windows Service." Once the user has entered valid account details for the domain user account into the Prepare IBM MQ Wizard, it configures an IBM MQ Windows service to run under the new account. The account details are held in the secure part of the Registry and cannot be read by users.

When the service is running, an IBM MQ Windows service is launched and remains running for as long as the service is running. An IBM MQ administrator who logs on to the server after the Windows service is launched can use the MQ Explorer to administer queue managers on the server. This connects the MQ Explorer to the existing Windows service process. These two actions need different levels of permission before they can work:

- The launch process requires a launch permission.
- The IBM MQ administrator requires Access permission.

User rights required for an IBM MQ Windows Service

The table in this topic lists the user rights required for the local and domain user account under which the Windows service for an IBM MQ installation runs.

Log on as batch job	Enables an IBM MQ Windows service to run under this user account.
Log on as service	Enables users to set the IBM MQ Windows service to log on using the configured account.
Shut down the system	Allows the IBM MQ Windows service to restart the server if configured to do so when recovery of a service fails.
Increase quotas	Required for operating system **CreateProcessAsUser** call.
Act as part of the operating system	Required for operating system **LogonUser** call.
Bypass traverse checking	Required for operating system **LogonUser** call.
Replace a process level token	Required for operating system **LogonUser** call.

Note: Debug programs rights might be needed in environments running ASP and IIS applications. Your domain user account must have these Windows user rights set as effective user rights as listed in the Local Security Policy application. If they are not, set them using either the Local Security Policy application locally on the server, or by using the Domain Security Application domain wide.

Changing the user name associated with the IBM MQ Service

You might need to change the user name associated with the IBM MQ Service from MUSR_MQADMIN to something else. (For example, you might need to do this if your queue manager is associated with DB2®, which does not accept user names of more than 8 characters.)

Procedure

1. Create a new user account (for example **NEW_NAME**)
2. Use the Prepare IBM MQ Wizard to enter the details of the new user account.

Changing the password of the IBM MQ Windows service user account

About this task

To change the password of the IBM MQ Windows service local user account, perform the following steps:

Procedure

1. Identify the user the service is running under.
2. Stop the IBM MQ service from the Computer Management panel.
3. Change the required password in the same way that you would change the password of an individual.
4. Go to the properties for the IBM MQ service from the Computer Management panel.
5. Select the **Log On** Page.
6. Confirm that the account name specified matches the user for which the password was modified.
7. Type the password into the **Password** and **Confirm password** fields and click **OK**.

IBM MQ Windows service for an installation running under a domain user account:

About this task

If the IBM MQ Windows service for an installation is running under a domain user account, you can also change the password for the account as follows:

Procedure

1. Change the password for the domain account on the domain controller. You might need to ask your domain administrator to do this for you.
2. Follow the steps to modify the **Log On** page for the IBM MQ service.

   The user account that IBM MQ Windows service runs under executes any MQSC commands that are issued by user interface applications, or performed automatically on system startup, shutdown, or service recovery. This user account must therefore have IBM MQ administration rights. By default it is added to the local **mqm** group on the server. If this membership is removed, the IBM MQ Windows service does not work. For more information about user rights, see “User rights required for an IBM MQ Windows Service” on page 65

   If a security problem arises with the user account that the IBM MQ Windows service runs under, error messages and descriptions appear in the system event log.

Related concepts:

"Using Active directory (Windows only)" on page 65
In some network configurations, where user accounts are defined on domain controllers that are using Active Directory, the local user account IBM MQ is running under might not have the authority it requires to query the group membership of other domain user accounts. The Prepare IBM MQ Wizard identifies whether this is the case by carrying out tests and asking the user questions about the network configuration.

IBM MQ coordinating with Db2 as the resource manager

If you start your queue managers from the MQ Explorer, or are using IBM MQ V7, and are having problems when coordinating Db2, check your queue manager error logs.

Check your queue manager error logs for an error like the following:

```
23/09/2008 15:43:54 - Process(5508.1) User(MUSR_MQADMIN) Program(amqzxma0.exe)
Host(HOST_1) Installation(Installation1)
VMRF(7.1.0.0) QMgr(A.B.C)
AMQ7604: The XA resource manager 'DB2 MQBankDB database' was not available when called
for xa_open. The queue manager is continuing without this resource manager.
```

Explanation: The user ID (default name is MUSR_MQADMIN) which runs the IBM MQ Service process `amqsvc.exe` is still running with an access token which does not contain group membership information for the group DB2USERS.

Solve: After you have ensured that the IBM MQ Service user ID is a member of DB2USERS, use the following sequence of commands:

- stop the service.
- stop any other processes running under the same user ID.
- restart these processes.

Rebooting the machine would ensure the previous steps, but is not necessary.

Extending the MQ Explorer

IBM MQ for Windows and IBM MQ for Linux x86-64 provide an administration interface called the MQ Explorer to perform administration tasks as an alternative to using control or MQSC commands.

This information applies to IBM MQ for Windows, and IBM MQ for Linux x86-64 platforms only.

The MQ Explorer presents information in a style consistent with that of the Eclipse framework and the other plug-in applications that Eclipse supports.

Through extending the MQ Explorer, system administrators have the ability to customize the MQ Explorer to improve the way they administer IBM MQ.

For more information, see *Extending the MQ Explorer* in the MQ Explorer product documentation.

Using the IBM MQ Taskbar application (Windows only)

The IBM MQ Taskbar application displays an icon in the Windows system tray on the server. The icon provides you with the current status of IBM MQ and a menu from which you can perform some simple actions.

On Windows, the IBM MQ icon is in the system tray on the server and is overlaid with a color-coded status symbol, which can have one of the following meanings:

Green Working correctly; no alerts at present

Blue Indeterminate; IBM MQ is starting up or shutting down

Yellow
Alert; one or more services are failing or have already failed

To display the menu, right-click the IBM MQ icon. From the menu you can perform the following actions:

- Click **Open** to open the IBM MQ Alert Monitor
- Click **Exit** to exit the IBM MQ Taskbar application
- Click **IBM MQ Explorer** to start the IBM MQ Explorer
- Click **Stop IBM MQ** to stop IBM MQ
- Click **About IBM MQ** to display information about the IBM MQ Alert Monitor

The IBM MQ alert monitor application (Windows only)

The IBM MQ alert monitor is an error detection tool that identifies and records problems with IBM MQ on a local machine.

The alert monitor displays information about the current status of the local installation of an IBM MQ server. It also monitors the Windows Advanced Configuration and Power Interface (ACPI) and ensures the ACPI settings are enforced.

From the IBM MQ alert monitor, you can:

- Access the IBM MQ Explorer directly
- View information relating to all outstanding alerts
- Shut down the IBM MQ service on the local machine
- Route alert messages over the network to a configurable user account, or to a Windows workstation or server

Administering local IBM MQ objects

This section tells you how to administer local IBM MQ objects to support application programs that use the Message Queue Interface (MQI). In this context, local administration means creating, displaying, changing, copying, and deleting IBM MQ objects.

In addition to the approaches detailed in this section you can use the IBM MQ Explorer to administer local IBM MQ objects; see “Administration using the MQ Explorer” on page 56.

This section contains the following information:
- Application programs using the MQI
- “Performing local administration tasks using MQSC commands” on page 73
- “Working with queue managers” on page 82
- “Working with local queues” on page 84
- “Working with alias queues” on page 89
- “Working with model queues” on page 110
- “Working with services” on page 117
- “Managing objects for triggering” on page 124

Starting and stopping a queue manager

Use this topic as an introduction to stopping and starting a queue manager.

Starting a queue manager

To start a queue manager, use the **strmqm** command as follows:

```
strmqm saturn.queue.manager
```

On IBM MQ for Windows and IBM MQ for Linux (x86 and x86-64 platforms) systems, you can start a queue manager as follows:
1. Open the IBM MQ Explorer.
2. Select the queue manager from the Navigator View.
3. Click **Start** . The queue manager starts.

If the queue manager start-up takes more than a few seconds IBM MQ issues information messages intermittently detailing the start-up progress.

The **strmqm** command does not return control until the queue manager has started and is ready to accept connection requests.

Starting a queue manager automatically

In IBM MQ for Windows you can start a queue manager automatically when the system starts using the IBM MQ Explorer. For more information, see “Administration using the MQ Explorer” on page 56.

Stopping a queue manager

Use the **`endmqm`** command to stop a queue manager.

Note: You must use the **`endmqm`** command from the installation associated with the queue manager that you are working with. You can find out which installation a queue manager is associated with using the `dspmq -o installation` command.

For example, to stop a queue manager called QMB, enter the following command:

```
endmqm QMB
```

On IBM MQ for Windows and IBM MQ for Linux (x86 and x86-64 platforms) systems, you can stop a queue manager as follows:

1. Open the IBM MQ Explorer.
2. Select the queue manager from the Navigator View.
3. Click **Stop...** . The End Queue Manager panel is displayed.
4. Select Controlled, or Immediate.
5. Click **OK** . The queue manager stops.

Quiesced shutdown

By default, the **endmqm** command performs a quiesced shutdown of the specified queue manager. This might take a while to complete. A quiesced shutdown waits until all connected applications have disconnected.

Use this type of shutdown to notify applications to stop. If you issue:

```
endmqm -c QMB
```

you are not told when all applications have stopped. (An `endmqm -c QMB` command is equivalent to an `endmqm QMB` command.)

However, if you issue:

```
endmqm -w QMB
```

the command waits until all applications have stopped and the queue manager has ended.

Immediate shutdown

For an immediate shutdown any current MQI calls are allowed to complete, but any new calls fail. This type of shutdown does not wait for applications to disconnect from the queue manager.

For an immediate shutdown, type:

```
endmqm -i QMB
```

Preemptive shutdown

Note: Do not use this method unless all other attempts to stop the queue manager using the **endmqm** command have failed. This method can have unpredictable consequences for connected applications.

If an immediate shutdown does not work, you must resort to a *preemptive* shutdown, specifying the `-p` flag. For example:

```
endmqm -p QMB
```

This stops the queue manager immediately. If this method still does not work, see "Stopping a queue manager manually" on page 71 for an alternative solution.

For a detailed description of the **endmqm** command and its options, see endmqm.

If you have problems shutting down a queue manager

Problems in shutting down a queue manager are often caused by applications. For example, when applications:

- Do not check MQI return codes properly
- Do not request notification of a quiesce
- Terminate without disconnecting from the queue manager (by issuing an **MQDISC** call)

If a problem occurs when you stop the queue manager, you can break out of the **endmqm** command using Ctrl-C. You can then issue another **endmqm** command, but this time with a flag that specifies the type of shutdown that you require.

Stopping a queue manager manually

If the standard methods for stopping queue managers fail, try the methods described here.

The standard way of stopping queue managers is by using the **endmqm** command. To stop a queue manager manually, use one of the procedures described in this section. For details of how to perform operations on queue managers using control commands, see Creating and managing queue managers on distributed platforms.

Stopping queue managers in IBM MQ for Windows:

How to end the processes and the IBM MQ service, to stop queue managers in IBM MQ for Windows.

To stop a queue manager running under IBM MQ for Windows:

1. List the names (IDs) of the processes that are running, by using the Windows Task Manager.
2. End the processes by using Windows Task Manager, or the **taskkill** command, in the following order (if they are running):

AMQZMUC0	Critical process manager
AMQZXMA0	Execution controller
AMQZFUMA	OAM process
AMQZLAA0	LQM agents
AMQZLSA0	LQM agents
AMQZMUF0	Utility Manager
AMQZMGR0	Process controller
AMQZMUR0	Restartable process manager
AMQFQPUB	Publish Subscribe process
AMQFCXBA	Broker worker process
AMQRMPPA	Process pooling process
AMQCRSTA	Non-threaded responder job process
AMQCRS6B	LU62 receiver channel and client connection
AMQRRMFA	The repository process (for clusters)
AMQPCSEA	The command server
RUNMQTRM	Invoke a trigger monitor for a server
RUNMQDLQ	Invoke dead-letter queue handler
RUNMQCHI	The channel initiator process
RUNMQLSR	The channel listener process
AMQXSSVN	Shared memory servers

3. Stop the IBM MQ service from **Administration tools** > **Services** on the Windows Control Panel.
4. If you have tried all methods and the queue manager has not stopped, reboot your system.

The Windows Task Manager and the **tasklist** command give limited information about tasks. For more information to help to determine which processes relate to a particular queue manager, consider using a tool such as *Process Explorer* (procexp.exe), available for download from the Microsoft website at http://www.microsoft.com.

Stopping queue managers in IBM MQ for UNIX and Linux systems:

How to end the processes and the IBM MQ service, to stop queue managers in IBM MQ for UNIX and Linux. You can try the methods described here if the standard methods for stopping and removing queue managers fail.

To stop a queue manager running under IBM MQ for UNIX and Linux systems:

1. Find the process IDs of the queue manager programs that are still running by using the **ps** command. For example, if the queue manager is called `QMNAME`, use the following command:

   ```
   ps -ef | grep QMNAME
   ```

2. End any queue manager processes that are still running. Use the **kill** command, specifying the process IDs discovered by using the **ps** command.

   End the processes in the following order:

amqzmuc0	Critical process manager
amqzxma0	Execution controller
amqzfuma	OAM process
amqzlaa0	LQM agents
amqzlsa0	LQM agents
amqzmuf0	Utility Manager
amqzmur0	Restartable process manager
amqzmgr0	Process controller
amqfqpub	Publish Subscribe process
amqfcxba	Broker worker process
amqrmppa	Process pooling process
amqcrsta	Non-threaded responder job process
amqcrs6b	LU62 receiver channel and client connection
amqrrmfa	The repository process (for clusters)
amqpcsea	The command server
runmqtrm	Invoke a trigger monitor for a server
runmqdlq	Invoke dead-letter queue handler
runmqchi	The channel initiator process
runmqlsr	The channel listener process

Note: You can use the **`kill -9`** command to end processes that fail to stop.

If you stop the queue manager manually, FFST™ might be taken, and FDC files placed in `/var/mqm/errors`. Do not regard this as a defect in the queue manager.

The queue manager will restart normally, even after you have stopped it using this method.

Stopping MQI channels

When you issue a STOP CHANNEL command against a server-connection channel, you can choose what method to use to stop the client-connection channel. This means that a client channel issuing an MQGET wait call can be controlled, and you can decide how and when to stop the channel.

The STOP CHANNEL command can be issued with three modes, indicating how the channel is to be stopped:

Quiesce
Stops the channel after any current messages have been processed.

If sharing conversations is enabled, the IBM MQ MQI client becomes aware of the stop request in a timely manner; this time is dependent upon the speed of the network. The client application becomes aware of the stop request as a result of issuing a subsequent call to IBM MQ.

Force Stops the channel immediately.

Terminate
Stops the channel immediately. If the channel is running as a process, it can terminate the channel's process, or if the channel is running as a thread, its thread.

This is a multi-stage process. If mode terminate is used, an attempt is made to stop the server-connection channel, first with mode quiesce, then with mode force, and if necessary with mode terminate. The client can receive different return codes during the different stages of termination. If the process or thread is terminated, the client receives a communication error.

The return codes returned to the application vary according to the MQI call issued, and the STOP CHANNEL command issued. The client will receive either an MQRC_CONNECTION_QUIESCING or an MQRC_CONNECTION_BROKEN return code. If a client detects MQRC_CONNECTION_QUIESCING it should try to complete the current transaction and terminate. This is not possible with MQRC_CONNECTION_BROKEN. If the client does not complete the transaction and terminate fast enough it will get CONNECTION_BROKEN after a few seconds. A STOP CHANNEL command with MODE(FORCE) or MODE(TERMINATE) is more likely to result in a CONNECTION_BROKEN than with MODE(QUIESCE).

MQI channels

Performing local administration tasks using MQSC commands

This section introduces you to MQSC commands and tells you how to use them for some common tasks.

If you use IBM MQ for Windows or IBM MQ for Linux (x86 and x86-64 platforms), you can also perform the operations described in this section using the IBM MQ Explorer. See “Administration using the MQ Explorer” on page 56 for more information.

You can use MQSC commands to manage queue manager objects, including the queue manager itself, queues, process definitions, channels, client connection channels, listeners, services, namelists, clusters, and authentication information objects. This section deals with queue managers, queues, and process definitions; for an overview of channel, client connection channel, and listener objects, see Objects. For information about all the MQSC commands for managing queue manager objects, see “Script (MQSC) Commands” on page 74.

You issue MQSC commands to a queue manager using the **runmqsc** command. (For details of this command, see runmqsc.) You can do this interactively, issuing commands from a keyboard, or you can redirect the standard input device (`stdin`) to run a sequence of commands from an ASCII text file. In both cases, the format of the commands is the same. (For information about running the commands from a text file, see “Running MQSC commands from text files” on page 78.)

You can run the **runmqsc** command in three ways, depending on the flags set on the command:

- Verify a command without running it, where the MQSC commands are verified on a local queue manager, but are not run.
- Run a command on a local queue manager, where the MQSC commands are run on a local queue manager.
- Run a command on a remote queue manager, where the MQSC commands are run on a remote queue manager.

You can also run the command followed by a question mark to display the syntax.

Object attributes specified in MQSC commands are shown in this section in uppercase (for example, RQMNAME), although they are not case-sensitive. MQSC command attribute names are limited to eight characters. MQSC commands are available on other platforms, including IBM i and z/OS.

From IBM MQ Version 8.0, you can set a prompt of your choice by using the MQPROMPT environment variable. In addition to plain text, the MQPROMPT variable also allows environment variables to be inserted, by using `+VARNAME+ notation`, in the same manner as IBM MQ service object definitions (see "Defining a service object" on page 118). For example:

```
sh> export MQPROMPT="+USER+ @ +QMNAME+ @ +MQ_HOST_NAME+> "
sh> runmqsc MY.QMGR
5724-H72 (C) Copyright IBM Corp. 1994, 2014.
Starting MQSC for queue manager MY.QMGR.
username @ MY.QMGR @ aix1> DISPLAY QMSTATUS
```

MQSC commands are detailed in the MQSC commands section.

Related information:

runmqsc (run MQSC commands)

Script (MQSC) Commands

MQSC commands provide a uniform method of issuing human-readable commands on IBM MQ platforms. For information about *programmable command format* (PCF) commands, see "Introduction to Programmable Command Formats" on page 6.

The general format of the commands is shown in The MQSC commands.

You should observe the following rules when using MQSC commands:

- Each command starts with a primary parameter (a verb), and this is followed by a secondary parameter (a noun). This is then followed by the name or generic name of the object (in parentheses) if there is one, which there is on most commands. Following that, parameters can usually occur in any order; if a parameter has a corresponding value, the value must occur directly after the parameter to which it relates.

  Note: z/OS On z/OS, the secondary parameter does not have to be second.
- Keywords, parentheses, and values can be separated by any number of blanks and commas. A comma shown in the syntax diagrams can always be replaced by one or more blanks. There must be at least one blank immediately preceding each parameter (after the primary parameter) z/OS except on z/OS .
- Any number of blanks can occur at the beginning or end of the command, and between parameters, punctuation, and values. For example, the following command is valid:

  ```
  ALTER QLOCAL ('Account' )      TRIGDPTH ( 1)
  ```

  Blanks within a pair of quotation marks are significant.

- Additional commas can appear anywhere where blanks are allowed and are treated as if they were blanks (unless, of course, they are inside strings enclosed by quotation marks).
- Repeated parameters are not allowed. Repeating a parameter with its "NO" version, as in REPLACE NOREPLACE, is also not allowed.
- Strings that contain blanks, lowercase characters or special characters other than:
  - Period (.)
  - Forward slash (/)
  - Underscore (_)
  - Percent sign (%)

  must be enclosed in single quotation marks, unless they are:
  - z/OS Issued from the IBM MQ for z/OS operations and control panels
  - Generic values ending with an asterisk IBM i (on IBM i these must be enclosed in single quotation marks)
  - A single asterisk (for example, TRACE(*)) IBM i (on IBM i these must be enclosed in single quotation marks)
  - A range specification containing a colon (for example, CLASS(01:03))

  If the string itself contains a single quotation mark, the single quotation mark is represented by two single quotation marks. Lowercase characters not contained within quotation marks are folded to uppercase.
- On platforms other than z/OS, a string containing no characters (that is, two single quotation marks with no space in between) is interpreted as a blank space enclosed in single quotation marks, that is, interpreted in the same way as (' '). The exception to this is if the attribute being used is one of the following:
  - `TOPICSTR`
  - `SUB`
  - `USERDATA`
  - `SELECTOR`

  then two single quotation marks with no space are interpreted as a zero-length string.

  z/OS On z/OS, if you want a blank space enclosed in single quotation marks, you must enter it as such (' '). A string containing no characters ('') is the same as entering ().
- In v7.0, any trailing blanks in those string attributes which are based on MQCHARV types, such as SELECTOR, sub user data, are treated as significant which means that 'abc ' does not equal 'abc'.
- A left parenthesis followed by a right parenthesis, with no significant information in between, for example

  ```
  NAME ( )
  ```

  is not valid except where specifically noted.
- Keywords are not case sensitive: AltER, alter, and ALTER are all acceptable. Anything that is not contained within quotation marks is folded to uppercase.
- Synonyms are defined for some parameters. For example, DEF is always a synonym for DEFINE, so DEF QLOCAL is valid. Synonyms are not, however, just minimum strings; DEFI is not a valid synonym for DEFINE.

  Note: There is no synonym for the DELETE parameter. This is to avoid accidental deletion of objects when using DEF, the synonym for DEFINE.

For an overview of using MQSC commands for administering IBM MQ, see “Performing local administration tasks using MQSC commands” on page 73.

MQSC commands use certain special characters to have certain meanings. For more information about these special characters and how to use them, see Characters with special meanings.

To find out how you can build scripts using MQSC commands, see Building command scripts.

z/OS For an explanation of the symbols in the z/OS column, see Using commands on z/OS.

For the full list of MQSC commands, see The MQSC commands.

Related information:

Building command scripts

IBM MQ object names

How to use object names in MQSC commands.

In examples, we use some long names for objects. This is to help you identify the type of object you are dealing with.

When you issue MQSC commands, you need specify only the local name of the queue. In our examples, we use queue names such as:

```
ORANGE.LOCAL.QUEUE
```

The `LOCAL.QUEUE` part of the name is to illustrate that this queue is a local queue. It is ***not*** required for the names of local queues in general.

We also use the name `saturn.queue.manager` as a queue manager name. The `queue.manager` part of the name is to illustrate that this object is a queue manager. It is *not* required for the names of queue managers in general.

Case-sensitivity in MQSC commands

MQSC commands, including their attributes, can be written in uppercase or lowercase. Object names in MQSC commands are folded to uppercase (that is, QUEUE and queue are not differentiated), unless the names are enclosed within single quotation marks. If quotation marks are not used, the object is processed with a name in uppercase. See Characters with special meanings for more information.

The **runmqsc** command invocation, in common with all IBM MQ control commands, is case sensitive in some IBM MQ environments. See Using control commands for more information.

Standard input and output

The *standard input device*, also referred to as `stdin`, is the device from which input to the system is taken. Typically this is the keyboard, but you can specify that input is to come from a serial port or a disk file, for example. The *standard output device*, also referred to as `stdout`, is the device to which output from the system is sent. Typically this is a display, but you can redirect output to a serial port or a file.

On operating-system commands and IBM MQ control commands, the < operator redirects input. If this operator is followed by a file name, input is taken from the file. Similarly, the > operator redirects output; if this operator is followed by a file name, output is directed to that file.

Using MQSC commands interactively

You can use MQSC commands interactively by using a command window or shell.

To use MQSC commands interactively, open a command window or shell and enter:

```
runmqsc
```

In this command, a queue manager name has not been specified, so the MQSC commands are processed by the default queue manager. If you want to use a different queue manager, specify the queue manager name on the **runmqsc** command. For example, to run MQSC commands on queue manager `jupiter.queue.manager`, use the command:

```
runmqsc jupiter.queue.manager
```

After this, all the MQSC commands you type in are processed by this queue manager, assuming that it is on the same node and is already running.

Now you can type in any MQSC commands, as required. For example, try this one:

```
DEFINE QLOCAL (ORANGE.LOCAL.QUEUE)
```

For commands that have too many parameters to fit on one line, use continuation characters to indicate that a command is continued on the following line:

- A minus sign (-) indicates that the command is to be continued from the start of the following line.
- A plus sign (+) indicates that the command is to be continued from the first nonblank character on the following line.

Command input terminates with the final character of a nonblank line that is not a continuation character. You can also terminate command input explicitly by entering a semicolon (;). (This is especially useful if you accidentally enter a continuation character at the end of the final line of command input.)

Feedback from MQSC commands

When you issue MQSC commands, the queue manager returns operator messages that confirm your actions or tell you about the errors you have made. For example:

```
AMQ8006: IBM MQ queue created.
```

This message confirms that a queue has been created.

```
AMQ8405: Syntax error detected at or near end of command segment below:-

AMQ8426: Valid MQSC commands are:

ALTER
CLEAR
DEFINE
DELETE
DISPLAY
END
PING
REFRESH
RESET
RESOLVE
RESUME
START
STOP
SUSPEND
4 : end
```

This message indicates that you have made a syntax error.

These messages are sent to the standard output device. If you have not entered the command correctly, refer to MQSC commands for the correct syntax.

Ending interactive input of MQSC commands

To stop working with MQSC commands, enter the END command.

Alternatively, you can use the EOF character for your operating system.

Running MQSC commands from text files

Running MQSC commands interactively is suitable for quick tests, but if you have very long commands, or are using a particular sequence of commands repeatedly, consider redirecting `stdin` from a text file.

"Standard input and output" on page 76 contains information about `stdin` and `stdout`. To redirect `stdin` from a text file, first create a text file containing the MQSC commands using your usual text editor. When you use the **runmqsc** command, use the redirection operators. For example, the following command runs a sequence of commands contained in the text file `myprog.in`:

```
runmqsc < myprog.in
```

Similarly, you can also redirect the output to a file. A file containing the MQSC commands for input is called an *MQSC command file*. The output file containing replies from the queue manager is called the *output file*.

To redirect both `stdin` and `stdout` on the **runmqsc** command, use this form of the command:

```
runmqsc < myprog.in > myprog.out
```

This command invokes the MQSC commands contained in the MQSC command file `myprog.in.` Because we have not specified a queue manager name, the MQSC commands run against the default queue manager. The output is sent to the text file `myprog.out`. Figure 11 on page 79 shows an extract from the MQSC command file `myprog.in` and Figure 12 on page 80 shows the corresponding extract of the output in `myprog.out`.

To redirect `stdin` and `stdout` on the **runmqsc** command, for a queue manager (`saturn.queue.manager`) that is not the default, use this form of the command:

```
runmqsc saturn.queue.manager < myprog.in > myprog.out
```

MQSC command files

MQSC commands are written in human-readable form, that is, in ASCII text. Figure 11 on page 79 is an extract from an MQSC command file showing an MQSC command (DEFINE QLOCAL) with its attributes. MQSC commands contains a description of each MQSC command and its syntax.

```
.
.
.
DEFINE QLOCAL(ORANGE.LOCAL.QUEUE) REPLACE +
DESCR(' ') +
PUT(ENABLED) +
DEFPRTY(0) +
DEFPSIST(NO) +
GET(ENABLED) +
MAXDEPTH(5000) +
MAXMSGL(1024) +
DEFSOPT(SHARED) +
NOHARDENBO +
USAGE(NORMAL) +
NOTRIGGER;
.
.
.
```

Figure 11. Extract from an MQSC command file

For portability among IBM MQ environments, limit the line length in MQSC command files to 72 characters. The plus sign indicates that the command is continued on the next line.

MQSC command reports

The **runmqsc** command returns a *report*, which is sent to `stdout`. The report contains:

- A header identifying MQSC commands as the source of the report:

  ```
  Starting MQSC for queue manager jupiter.queue.manager.
  ```

  Where `jupiter.queue.manager` is the name of the queue manager.
- An optional numbered listing of the MQSC commands issued. By default, the text of the input is echoed to the output. Within this output, each command is prefixed by a sequence number, as shown in Figure 12 on page 80. However, you can use the -e flag on the **runmqsc** command to suppress the output.
- A syntax error message for any commands found to be in error.
- An *operator message* indicating the outcome of running each command. For example, the operator message for the successful completion of a DEFINE QLOCAL command is:

  ```
  AMQ8006: IBM MQ queue created.
  ```
- Other messages resulting from general errors when running the script file.
- A brief statistical summary of the report indicating the number of commands read, the number of commands with syntax errors, and the number of commands that could not be processed.

  Note: The queue manager attempts to process only those commands that have no syntax errors.

```
Starting MQSC for queue manager jupiter.queue.manager.
.
.
12:   DEFINE QLOCAL('ORANGE.LOCAL.QUEUE') REPLACE +
:       DESCR(' ') +
:       PUT(ENABLED) +
:       DEFPRTY(0) +
:       DEFPSIST(NO) +
:       GET(ENABLED) +
:       MAXDEPTH(5000) +
:       MAXMSGL(1024) +
:       DEFSOPT(SHARED) +
:       NOHARDENBO +
:       USAGE(NORMAL) +
:       NOTRIGGER;
AMQ8006: IBM MQ queue created.

```

Figure 12. Extract from an MQSC command report file

Running the supplied MQSC command files

The following MQSC command files are supplied with IBM MQ:

amqscos0.tst
Definitions of objects used by sample programs.

amqscic0.tst
Definitions of queues for CICS® transactions.

In IBM MQ for Windows, these files are located in the directory *MQ_INSTALLATION_PATH*\tools\mqsc\samples. *MQ_INSTALLATION_PATH* represents the high-level directory in which IBM MQ is installed.

On UNIX and Linux systems these files are located in the directory *MQ_INSTALLATION_PATH*/samp. *MQ_INSTALLATION_PATH* represents the high-level directory in which IBM MQ is installed.

The command that runs them is:

```
runmqsc < amqscos0.tst >test.out
```

Using runmqsc to verify commands

You can use the **runmqsc** command to verify MQSC commands on a local queue manager without actually running them. To do this, set the -v flag in the **runmqsc** command, for example:

```
runmqsc -v < myprog.in > myprog.out
```

When you invoke **runmqsc** against an MQSC command file, the queue manager verifies each command and returns a report without actually running the MQSC commands. This allows you to check the syntax of the commands in your command file. This is particularly important if you are:

- Running a large number of commands from a command file.
- Using an MQSC command file many times over.

The returned report is similar to that shown in Figure 12.

You cannot use this method to verify MQSC commands remotely. For example, if you attempt this command:

```
runmqsc -w 30 -v jupiter.queue.manager < myprog.in > myprog.out
```

the -w flag, which you use to indicate that the queue manager is remote, is ignored, and the command is run locally in verification mode. 30 is the number of seconds that IBM MQ waits for replies from the remote queue manager.

Running MQSC commands from batch files

If you have very long commands, or are using a particular sequence of commands repeatedly, consider redirecting `stdin` from a batch file.

To redirect `stdin` from a batch file, first create a batch file containing the MQSC commands using your usual text editor. When you use the **runmqsc** command, use the redirection operators. The following example:

1. Creates a test queue manager, TESTQM
2. Creates a matching CLNTCONN and listener set to use TCP/IP port 1600
3. Creates a test queue, TESTQ
4. Puts a message on the queue, using the amqsputc sample program

```
export MYTEMPQM=TESTQM
export MYPORT=1600
export MQCHLLIB=/var/mqm/qmgrs/$MQTEMPQM/@ipcc

crtmqm $MYTEMPQM
strmqm $MYTEMPQM
runmqlsr -m $MYTEMPQM -t TCP -p $MYPORT &

runmqsc $MYTEMPQM << EOF
DEFINE CHANNEL(NTLM) CHLTYPE(SVRCONN) TRPTYPE(TCP)
DEFINE CHANNEL(NTLM) CHLTYPE(CLNTCONN) QMNAME('$MYTEMPQM') CONNAME('hostname($MYPORT)')
ALTER CHANNEL(NTLM) CHLTYPE(CLNTCONN)
DEFINE QLOCAL(TESTQ)
EOF

amqsputc TESTQ $MYTEMPQM << EOF
hello world
EOF

endmqm -i $MYTEMPQM
```

Figure 13. Example script for running MQSC commands from a batch file

Resolving problems with MQSC commands

If you cannot get MQSC commands to run, use the information in this topic to see if any of these common problems apply to you. It is not always obvious what the problem is when you read the error that a command generates.

When you use the **runmqsc** command, remember the following:

- Use the < operator to redirect input from a file. If you omit this operator, the queue manager interprets the file name as a queue manager name, and issues the following error message:

  ```
  AMQ8118: IBM MQ queue manager does not exist.
  ```
- If you redirect output to a file, use the > redirection operator. By default, the file is put in the current working directory at the time **runmqsc** is invoked. Specify a fully-qualified file name to send your output to a specific file and directory.
- Check that you have created the queue manager that is going to run the commands, by using the following command to display all queue managers:

  ```
  dspmq
  ```
- The queue manager must be running. If it is not, start it; (see Starting a queue manager). You get an error message if you try to start a queue manager that is already running.

- Specify a queue manager name on the **runmqsc** command if you have not defined a default queue manager, or you get this error:

```
AMQ8146: IBM MQ queue manager not available.
```

- You cannot specify an MQSC command as a parameter of the **runmqsc** command. For example, this is not valid:

```
runmqsc DEFINE QLOCAL(FRED)
```

- You cannot enter MQSC commands before you issue the **runmqsc** command.
- You cannot run control commands from **runmqsc** . For example, you cannot issue the **strmqm** command to start a queue manager while you are running MQSC commands interactively. If you do this, you receive error messages similar to the following:

```
runmqsc
.
.
Starting MQSC for queue manager jupiter.queue.manager.

1 : strmqm saturn.queue.manager
AMQ8405: Syntax error detected at or near end of cmd segment below:-s

AMQ8426: Valid MQSC commands are:
ALTER
CLEAR
DEFINE
DELETE
DISPLAY
END
PING
REFRESH
RESET
RESOLVE
RESUME
START
STOP
SUSPEND
2 : end
```

Working with queue managers

Examples of MQSC commands that you can use to display or alter queue manager attributes.

Displaying queue manager attributes

To display the attributes of the queue manager specified on the **runmqsc** command, use the following MQSC command:

```
DISPLAY QMGR
```

Typical output from this command is shown in Figure 14 on page 83

```
DISPLAY QMGR
     1 : DISPLAY QMGR
AMQ8408: Display Queue Manager details.
   QMNAME(QM1)                            ACCTCONO(DISABLED)

   REPOS( )                               REPOSNL( )
   ROUTEREC(MSG)                          SCHINIT(QMGR)
   SCMDSERV(QMGR)                         SSLCRLNL( )
   SSLCRYP( )                             SSLEV(DISABLED)
   SSLFIPS(NO)                            SSLKEYR(C:\Program Files\IBM\WebSphere
MQ\Data\qmgrs\QM1\ssl\key)
   SSLRKEYC(0)                            STATACLS(QMGR)
   STATCHL(OFF)                           STATINT(1800)
   STATMQI(OFF)                           STATQ(OFF)
   STRSTPEV(ENABLED)                      SYNCPT
   TREELIFE(1800)                         TRIGINT(999999999)
```

Figure 14. Typical output from a DISPLAY QMGR command

The `ALL` parameter is the default on the `DISPLAY QMGR` command. It displays all the queue manager attributes. In particular, the output tells you the default queue manager name, the dead-letter queue name, and the command queue name.

You can confirm that these queues exist by entering the command:

```
DISPLAY QUEUE (SYSTEM.*)
```

This displays a list of queues that match the stem `SYSTEM.*`. The parentheses are required.

Altering queue manager attributes

To alter the attributes of the queue manager specified on the **runmqsc** command, use the MQSC command `ALTER QMGR`, specifying the attributes and values that you want to change. For example, use the following commands to alter the attributes of `jupiter.queue.manager`:

```
runmqsc jupiter.queue.manager
ALTER QMGR DEADQ (ANOTHERDLQ) INHIBTEV (ENABLED)
```

The `ALTER QMGR` command changes the dead-letter queue used, and enables inhibit events.

Attributes for the queue manager

Working with local queues

This section contains examples of some MQSC commands that you can use to manage local, model, and alias queues.

See MQSC commands for detailed information about these commands.

Defining a local queue

For an application, the local queue manager is the queue manager to which the application is connected. Queues managed by the local queue manager are said to be local to that queue manager.

Use the MQSC command DEFINE QLOCAL to create a local queue. You can also use the default defined in the default local queue definition, or you can modify the queue characteristics from those of the default local queue.

Note: The default local queue is named SYSTEM.DEFAULT.LOCAL.QUEUE and it was created on system installation.

For example, the DEFINE QLOCAL command that follows defines a queue called ORANGE.LOCAL.QUEUE with these characteristics:

- It is enabled for gets, enabled for puts, and operates on a priority order basis.
- It is an *normal* queue; it is not an initiation queue or transmission queue, and it does not generate trigger messages.
- The maximum queue depth is 5000 messages; the maximum message length is 4194304 bytes.

```
DEFINE QLOCAL (ORANGE.LOCAL.QUEUE) +
DESCR('Queue for messages from other systems') +
PUT (ENABLED) +
GET (ENABLED) +
NOTRIGGER +
MSGDLVSQ (PRIORITY) +
MAXDEPTH (5000) +
MAXMSGL (4194304) +
USAGE (NORMAL);
```

Note:

1. With the exception of the value for the description, all the attribute values shown are the default values. We have shown them here for purposes of illustration. You can omit them if you are sure that the defaults are what you want or have not been changed. See also "Displaying default object attributes" on page 85.
2. USAGE (NORMAL) indicates that this queue is not a transmission queue.
3. If you already have a local queue on the same queue manager with the name ORANGE.LOCAL.QUEUE, this command fails. Use the REPLACE attribute if you want to overwrite the existing definition of a queue, but see also "Changing local queue attributes" on page 86.

Displaying default object attributes

You can use the DISPLAY QUEUE command to display attributes that were taken from the default object when an IBM MQ object was defined.

When you define an IBM MQ object, it takes any attributes that you do not specify from the default object. For example, when you define a local queue, the queue inherits any attributes that you omit in the definition from the default local queue, which is called SYSTEM.DEFAULT.LOCAL.QUEUE. To see exactly what these attributes are, use the following command:

```
DISPLAY QUEUE (SYSTEM.DEFAULT.LOCAL.QUEUE)
```

The syntax of this command is different from that of the corresponding DEFINE command. On the DISPLAY command you can give just the queue name, whereas on the DEFINE command you have to specify the type of the queue, that is, QLOCAL, QALIAS, QMODEL, or QREMOTE.

You can selectively display attributes by specifying them individually. For example:

```
DISPLAY QUEUE (ORANGE.LOCAL.QUEUE) +
MAXDEPTH +
MAXMSGL +
CURDEPTH;
```

This command displays the three specified attributes as follows:

```
AMQ8409: Display Queue details.
QUEUE(ORANGE.LOCAL.QUEUE)       TYPE(QLOCAL)
CURDEPTH(0)              MAXDEPTH(5000)
MAXMSGL(4194304)
```

CURDEPTH is the current queue depth, that is, the number of messages on the queue. This is a useful attribute to display, because by monitoring the queue depth you can ensure that the queue does not become full.

Copying a local queue definition

You can copy a queue definition using the LIKE attribute on the DEFINE command.

For example:

```
DEFINE QLOCAL (MAGENTA.QUEUE) +
LIKE (ORANGE.LOCAL.QUEUE)
```

This command creates a queue with the same attributes as our original queue ORANGE.LOCAL.QUEUE, rather than those of the system default local queue. Enter the name of the queue to be copied ***exactly*** as it was entered when you created the queue. If the name contains lower case characters, enclose the name in single quotation marks.

You can also use this form of the DEFINE command to copy a queue definition, but substitute one or more changes to the attributes of the original. For example:

```
DEFINE QLOCAL (THIRD.QUEUE) +
LIKE (ORANGE.LOCAL.QUEUE) +
MAXMSGL(1024);
```

This command copies the attributes of the queue ORANGE.LOCAL.QUEUE to the queue THIRD.QUEUE, but specifies that the maximum message length on the new queue is to be 1024 bytes, rather than 4194304.

Note:

1. When you use the LIKE attribute on a DEFINE command, you are copying the queue attributes only. You are not copying the messages on the queue.

2. If you a define a local queue, without specifying LIKE, it is the same as DEFINE LIKE(SYSTEM.DEFAULT.LOCAL.QUEUE).

Changing local queue attributes

You can change queue attributes in two ways, using either the ALTER QLOCAL command or the DEFINE QLOCAL command with the REPLACE attribute.

In "Defining a local queue" on page 84, the queue called ORANGE.LOCAL.QUEUE was defined. Suppose, for example, that you want to decrease the maximum message length on this queue to 10,000 bytes.

- Using the ALTER command:

  ```
  ALTER QLOCAL (ORANGE.LOCAL.QUEUE) MAXMSGL(10000)
  ```

  This command changes a single attribute, that of the maximum message length; all the other attributes remain the same.
- Using the DEFINE command with the REPLACE option, for example:

  ```
  DEFINE QLOCAL (ORANGE.LOCAL.QUEUE) MAXMSGL(10000) REPLACE
  ```

  This command changes not only the maximum message length, but also all the other attributes, which are given their default values. The queue is now put enabled whereas previously it was put inhibited. Put enabled is the default, as specified by the queue SYSTEM.DEFAULT.LOCAL.QUEUE.

  If you ***decrease*** the maximum message length on an existing queue, existing messages are not affected. Any new messages, however, must meet the new criteria.

Clearing a local queue

You can use the CLEAR command to clear a local queue.

To delete all the messages from a local queue called MAGENTA.QUEUE, use the following command:

```
CLEAR QLOCAL (MAGENTA.QUEUE)
```

Note: There is no prompt that enables you to change your mind; once you press the Enter key the messages are lost.

You cannot clear a queue if:

- There are uncommitted messages that have been put on the queue under sync point.
- An application currently has the queue open.

Deleting a local queue

You can use the MQSC command DELETE QLOCAL to delete a local queue.

A queue cannot be deleted if it has uncommitted messages on it. However, if the queue has one or more committed messages and no uncommitted messages, it can be deleted only if you specify the PURGE option. For example:

```
DELETE QLOCAL (PINK.QUEUE) PURGE
```

Specifying NOPURGE instead of PURGE ensures that the queue is not deleted if it contains any committed messages.

Browsing queues

IBM MQ provides a sample queue browser that you can use to look at the contents of the messages on a queue. The browser is supplied in both source and executable formats.

`MQ_INSTALLATION_PATH` represents the high-level directory in which IBM MQ is installed.

In IBM MQ for Windows, the file names and paths for the sample queue browser are as follows:

Source
: `MQ_INSTALLATION_PATH\tools\c\samples\`

Executable
: `MQ_INSTALLATION_PATH\tools\c\samples\bin\amqsbcg.exe`

In IBM MQ for UNIX and Linux, the file names and paths are as follows:

Source
: `MQ_INSTALLATION_PATH/samp/amqsbcg0.c`

Executable
: `MQ_INSTALLATION_PATH/samp/bin/amqsbcg`

The sample requires two input parameters, the queue name and the queue manager name. For example:

```
amqsbcg SYSTEM.ADMIN.QMGREVENT.tpp01 saturn.queue.manager
```

Typical results from this command are shown in Figure 15 on page 88.

```

Enabling large queues

IBM MQ supports queues larger than 2 GB.

On Windows systems, support for large files is available without any additional enablement. On AIX, HP-UX, Linux, and Solaris systems, you need to explicitly enable large file support before you can create queue files larger than 2 GB. See your operating system documentation for information on how to do this.

Some utilities, such as tar, cannot cope with files greater than 2 GB. Before enabling large file support, check your operating system documentation for information on restrictions on utilities you use.

For information about planning the amount of storage you need for queues, visit the IBM MQ website for platform-specific performance reports: `http://www.ibm.com/support/docview.wss?rs=171&uid=swg27007150&loc=en_US&cs=utf-8&lang=en#1`

Working with alias queues

You can define an alias queue to refer indirectly to another queue or topic.

V 8.0.0.6

Attention: Distribution lists do not support the use of alias queues that point to topic objects. From Version 8.0.0, Fix Pack 6, if an alias queue points to a topic object in a distribution list, IBM MQ returns MQRC_ALIAS_BASE_Q_TYPE_ERROR.

The queue to which an alias queue refers can be any of the following:
- A local queue (see "Defining a local queue" on page 84).
- A local definition of a remote queue (see "Creating a local definition of a remote queue" on page 137).
- A topic.

An alias queue is not a real queue, but a definition that resolves to a real (or target) queue at run time. The alias queue definition specifies the target queue. When an application makes an **MQOPEN** call to an alias queue, the queue manager resolves the alias to the target queue name.

An alias queue cannot resolve to another locally defined alias queue. However, an alias queue can resolve to alias queues that are defined elsewhere in clusters of which the local queue manager is a member. See Name resolution for further information.

Alias queues are useful for:
- Giving different applications different levels of access authorities to the target queue.
- Allowing different applications to work with the same queue in different ways. (Perhaps you want to assign different default priorities or different default persistence values.)
- Simplifying maintenance, migration, and workload balancing. (Perhaps you want to change the target queue name without having to change your application, which continues to use the alias.)

For example, assume that an application has been developed to put messages on a queue called MY.ALIAS.QUEUE. It specifies the name of this queue when it makes an **MQOPEN** request and, indirectly, if it puts a message on this queue. The application is not aware that the queue is an alias queue. For each MQI call using this alias, the queue manager resolves the real queue name, which could be either a local queue or a remote queue defined at this queue manager.

By changing the value of the TARGQ attribute, you can redirect MQI calls to another queue, possibly on another queue manager. This is useful for maintenance, migration, and load-balancing.

Defining an alias queue

The following command creates an alias queue:

```
DEFINE QALIAS (MY.ALIAS.QUEUE) TARGET (YELLOW.QUEUE)
```

This command redirects MQI calls that specify MY.ALIAS.QUEUE to the queue YELLOW.QUEUE. The command does not create the target queue; the MQI calls fail if the queue YELLOW.QUEUE does not exist at run time.

If you change the alias definition, you can redirect the MQI calls to another queue. For example:

```
ALTER QALIAS (MY.ALIAS.QUEUE) TARGET (MAGENTA.QUEUE)
```

This command redirects MQI calls to another queue, MAGENTA.QUEUE.

You can also use alias queues to make a single queue (the target queue) appear to have different attributes for different applications. You do this by defining two aliases, one for each application. Suppose there are two applications:

- Application ALPHA can put messages on YELLOW.QUEUE, but is not allowed to get messages from it.
- Application BETA can get messages from YELLOW.QUEUE, but is not allowed to put messages on it.

The following command defines an alias that is put enabled and get disabled for application ALPHA:

```
DEFINE QALIAS (ALPHAS.ALIAS.QUEUE) +
TARGET (YELLOW.QUEUE) +
PUT (ENABLED) +
GET (DISABLED)
```

The following command defines an alias that is put disabled and get enabled for application BETA:

```
DEFINE QALIAS (BETAS.ALIAS.QUEUE) +
TARGET (YELLOW.QUEUE) +
PUT (DISABLED) +
GET (ENABLED)
```

ALPHA uses the queue name ALPHAS.ALIAS.QUEUE in its MQI calls; BETA uses the queue name BETAS.ALIAS.QUEUE. They both access the same queue, but in different ways.

You can use the LIKE and REPLACE attributes when you define queue aliases, in the same way that you use these attributes with local queues.

Using other commands with alias queues

You can use the appropriate MQSC commands to display or alter alias queue attributes, or to delete the alias queue object. For example:

Use the following command to display the alias queue's attributes:

```
DISPLAY QUEUE (ALPHAS.ALIAS.QUEUE)
```

Use the following command to alter the base queue name, to which the alias resolves, where the `force` option forces the change even if the queue is open:

```
ALTER QALIAS (ALPHAS.ALIAS.QUEUE) TARGQ(ORANGE.LOCAL.QUEUE) FORCE
```

Use the following command to delete this queue alias:

```
DELETE QALIAS (ALPHAS.ALIAS.QUEUE)
```

You cannot delete an alias queue if an application currently has the queue open. See MQSC commands for more information about this, and other alias queue commands.

Working with dead-letter queues

Each queue manager typically has a local queue to use as a dead-letter queue, so that messages that cannot be delivered to their correct destination can be stored for later retrieval. You tell the queue manager about the dead-letter queue, and specify how messages found on a dead-letter queue are to be processed. Using dead-letter queues can affect the sequence in which messages are delivered, so you might choose not to use them.

To tell the queue manager about the dead-letter queue, specify a dead-letter queue name on the **crtmqm** command (`crtmqm -u DEAD.LETTER.QUEUE`, for example), or by using the DEADQ attribute on the ALTER QMGR command to specify one later. You must define the dead-letter queue before using it.

A sample dead-letter queue called SYSTEM.DEAD.LETTER.QUEUE is available with the product. This queue is automatically created when you create the queue manager. You can modify this definition if required, and rename it.

A dead-letter queue has no special requirements except that:
- It must be a local queue
- Its MAXMSGL (maximum message length) attribute must enable the queue to accommodate the largest messages that the queue manager has to handle **plus** the size of the dead-letter header (MQDLH)

Using dead-letter queues can affect the sequence in which messages are delivered, so you might choose not to use them. You set the USEDLQ channel attribute to determine whether the dead-letter queue is used when messages cannot be delivered. This attribute can be configured so that some functions of the queue manager use the dead-letter queue, while other functions do not. For more information about the use of the USEDLQ channel attribute on different MQSC commands, see DEFINE CHANNEL, DISPLAY CHANNEL, ALTER CHANNEL, and DISPLAY CLUSQMGR.

IBM MQ provides a dead-letter queue handler that allows you to specify how messages found on a dead-letter queue are to be processed or removed. See "Processing messages on a dead-letter queue."

Undelivered messages troubleshooting

Processing messages on a dead-letter queue

To process messages on a dead-letter queue (DLQ), MQ supplies a default DLQ handler. The handler matches messages on the DLQ against entries in a rules table that you define.

Messages can be put on a DLQ by queue managers, message channel agents (MCAs), and applications. All messages on the DLQ must be prefixed with a *dead-letter header* structure, MQDLH. Messages put on the DLQ by a queue manager or a message channel agent always have this header; applications putting messages on the DLQ must supply this header. The *Reason* field of the MQDLH structure contains a reason code that identifies why the message is on the DLQ.

All IBM MQ environments need a routine to process messages on the DLQ regularly. IBM MQ supplies a default routine, called the *dead-letter queue handler* (the DLQ handler), which you invoke using the **runmqdlq** command.

Instructions for processing messages on the DLQ are supplied to the DLQ handler by means of a user-written *rules table*. That is, the DLQ handler matches messages on the DLQ against entries in the rules table; when a DLQ message matches an entry in the rules table, the DLQ handler performs the action associated with that entry.

Dead-letter queues
Undelivered messages troubleshooting

The IBM MQ for IBM i dead-letter queue handler:

Use this information to learn about, and how to invoke, the dead-letter queue handler.

A *dead-letter queue* (DLQ), sometimes referred to as an *undelivered-message queue*, is a holding queue for messages that cannot be delivered to their destination queues. Every queue manager in a network should have an associated DLQ.

Note: It is often preferable to avoid placing messages on a DLQ. For information about the use and avoidance of DLQs, see "Working with dead-letter queues" on page 91.

Queue managers, message channel agents, and applications can put messages on the DLQ. All messages on the DLQ must be prefixed with a *dead-letter header* structure, MQDLH. Messages put on the DLQ by a queue manager or by a message channel agent always have an MQDLH. Always supply an MQDLH to applications putting messages on the DLQ. The *Reason* field of the MQDLH structure contains a reason code that identifies why the message is on the DLQ.

In all IBM MQ environments, there must be a routine that runs regularly to process messages on the DLQ. IBM MQ supplies a default routine, called the *dead-letter queue handler* (the DLQ handler), which you invoke using the STRMQMDLQ command. A user-written *rules table* supplies instructions to the DLQ handler, for processing messages on the DLQ. That is, the DLQ handler matches messages on the DLQ against entries in the rules table. When a DLQ message matches an entry in the rules table, the DLQ handler performs the action associated with that entry.

Invoking the DLQ handler

Use the STRMQMDLQ command to invoke the DLQ handler. You can name the DLQ that you want to process and the queue manager that you want to use in two ways:

- As parameters to STRMQMDLQ from the command prompt. For example:
  ```
  STRMQMDLQ UDLMSGQ(ABC1.DEAD.LETTER.QUEUE) SRCMBR(QRULE) SRCFILE(library/QTXTSRC)
  MQMNAME(MY.QUEUE.MANAGER)
  ```
- In the rules table. For example:
  ```
  INPUTQ(ABC1.DEAD.LETTER.QUEUE)
  ```

Note: The rules table is a member within a source physical file that can take any name.

The examples apply to the DLQ called `ABC1.DEAD.LETTER.QUEUE`, owned by the default queue manager.

If you do not specify the DLQ or the queue manager as shown, the default queue manager for the installation is used along with the DLQ belonging to that queue manager.

The STRMQMDLQ command takes its input from the rules table.

You must be authorized to access both the DLQ itself, and any message queues to which messages on the DLQ are forwarded, in order to run the DLQ handler. You must also be authorized to assume the identity of other users, for the DLQ to put messages on queues with the authority of the user ID in the message context.

Undelivered messages troubleshooting

The DLQ handler rules table:

The DLQ handler rules table defines how the DLQ handler is to process messages that arrive on the DLQ

The DLQ handler rules table defines how the DLQ handler is to process messages that arrive on the DLQ. There are two types of entry in a rules table:
- The first entry in the table, which is optional, contains *control data*.
- All other entries in the table are *rules* for the DLQ handler to follow. Each rule consists of a *pattern* (a set of message characteristics) that a message is matched against, and an *action* to be taken when a message on the DLQ matches the specified pattern. There must be at least one rule in a rules table.

Each entry in the rules table comprises one or more keywords.

Control data

This section describes the keywords that you can include in a control-data entry in a DLQ handler rules table. Note the following:
- The default value for a keyword, if any, is underlined.
- The vertical line (|) separates alternatives. You can specify only one of these.
- All keywords are optional.

INPUTQ (*QueueName* **|' ')**
The name of the DLQ you want to process:
1. Any UDLMSGQ value (or *DFT) you specify as a parameter to the **STRMQMDLQ** command overrides any INPUTQ value in the rules table.
2. If you specify a blank UDLMSGQ value as a parameter to the **STRMQMDLQ** command, the INPUTQ value in the rules table is used.
3. If you specify a blank UDLMSGQ value as a parameter to the **STRMQMDLQ** command, and a blank INPUTQ value in the rules table, the system default dead-letter queue is used.

INPUTQM (*QueueManagerName* **|' ')**
The name of the queue manager that owns the DLQ named on the INPUTQ keyword.

If you do not specify a queue manager, or you specify INPUTQM(' ') in the rules table, the system uses the default queue manager for the installation.

RETRYINT (*Interval* **|** <u>**60**</u> **)**
The interval, in seconds, at which the DLQ handler should attempt to reprocess messages on the DLQ that could not be processed at the first attempt, and for which repeated attempts have been requested. By default, the retry interval is 60 seconds.

WAIT (<u>**YES**</u> **|NO|** *nnn* **)**
Whether the DLQ handler should wait for further messages to arrive on the DLQ when it detects that there are no further messages that it can process.

YES Causes the DLQ handler to wait indefinitely.

NO Causes the DLQ handler to terminate when it detects that the DLQ is either empty or contains no messages that it can process.

nnn Causes the DLQ handler to wait for *nnn* seconds for new work to arrive before terminating, after it detects that the queue is either empty or contains no messages that it can process.

Specify WAIT (YES) for busy DLQs, and WAIT (NO) or WAIT (*nnn*) for DLQs that have a low level of activity. If the DLQ handler is allowed to terminate, re-invoke it using triggering.

You can supply the name of the DLQ as an input parameter to the **STRMQMDLQ** command, as an alternative to including control data in the rules table. If any value is specified both in the rules table and on input to the **STRMQMDLQ** command, the value specified on the **STRMQMDLQ** command takes precedence.

Note: If a control-data entry is included in the rules table, it ***must*** be the first entry in the table.

Rules (patterns and actions):

Use this information to understand the DLQ rules.

Here is an example rule from a DLQ handler rules table:

```
PERSIST(MQPER_PERSISTENT) REASON (MQRC_PUT_INHIBITED) +
ACTION (RETRY) RETRY (3)
```

This rule instructs the DLQ handler to make 3 attempts to deliver to its destination queue any persistent message that was put on the DLQ because MQPUT and MQPUT1 were inhibited.

This section describes the keywords that you can include in a rule. Note the following:

- The default value for a keyword, if any, is underlined. For most keywords, the default value is * (asterisk), which matches any value.
- The vertical line (|) separates alternatives. You can specify only one of these.
- All keywords except ACTION are optional.

This section begins with a description of the pattern-matching keywords (those against which messages on the DLQ are matched). It then describes the action keywords (those that determine how the DLQ handler is to process a matching message).

The pattern-matching keywords:

The pattern-matching keywords are described in the following example. Use them to specify values against which messages on the DLQ are matched. All pattern-matching keywords are optional.

APPLIDAT (*ApplIdentityData* **|** **<u>*</u>** **)**
The *ApplIdentityData* value of the message on the DLQ, specified in the message descriptor, MQMD.

APPLNAME (*PutApplName* **|** **<u>*</u>** **)**
The name of the application that issued the MQPUT or MQPUT1 call, as specified in the *PutApplName* field of the message descriptor, MQMD, of the message on the DLQ.

APPLTYPE (*PutApplType* **|** **<u>*</u>** **)**
The *PutApplType* value specified in the message descriptor, MQMD, of the message on the DLQ.

DESTQ (*QueueName* **|** **<u>*</u>** **)**
The name of the message queue for which the message is destined.

DESTQM (*QueueManagerName* **|** **<u>*</u>** **)**
The queue manager name for the message queue for which the message is destined.

FEEDBACK (*Feedback* **|** **<u>*</u>** **)**
When the *MsgType* value is MQMT_REPORT, *Feedback* describes the nature of the report.

You can use symbolic names. For example, you can use the symbolic name MQFB_COA to identify those messages on the DLQ that require confirmation of their arrival on their destination queues.

FORMAT (*Format* **|** **<u>*</u>** **)**
The name that the sender of the message uses to describe the format of the message data.

MSGTYPE (*MsgType* **|** ***** **)**
The message type of the message on the DLQ.

You can use symbolic names. For example, you can use the symbolic name MQMT_REQUEST to identify those messages on the DLQ that require replies.

PERSIST (*Persistence* **|** ***** **)**
The persistence value of the message. (The persistence of a message determines whether it survives restarts of the queue manager.)

You can use symbolic names. For example, you can use the symbolic name MQPER_PERSISTENT to identify those messages on the DLQ that are persistent.

REASON (*ReasonCode* **|** ***** **)**
The reason code that describes why the message was put to the DLQ.

You can use symbolic names. For example, you can use the symbolic name MQRC_Q_FULL to identify those messages placed on the DLQ because their destination queues were full.

REPLYQ (*QueueName* **|** ***** **)**
The reply-to queue name specified in the message descriptor, MQMD, of the message on the DLQ.

REPLYQM (*QueueManagerName* **|** ***** **)**
The queue manager name of the reply-to queue specified in the REPLYQ keyword.

USERID (*UserIdentifier* **|** ***** **)**
The user ID of the user who originated the message on the DLQ, as specified in the message descriptor, MQMD.

The action keywords:

The action keywords are described. Use them to determine how a matching message is processed.

ACTION (DISCARD|IGNORE|RETRY|FWD)
The action taken for any message on the DLQ that matches the pattern defined in this rule.

DISCARD
Causes the message to be deleted from the DLQ.

IGNORE
Causes the message to be left on the DLQ.

RETRY
Causes the DLQ handler to try again to put the message on its destination queue.

FWD Causes the DLQ handler to forward the message to the queue named on the FWDQ keyword.

You must specify the ACTION keyword. The number of attempts made to implement an action is governed by the RETRY keyword. The RETRYINT keyword of the control data controls the interval between attempts.

FWDQ (*QueueName* **|&DESTQ|&REPLYQ)**
The name of the message queue to which the message is forwarded when you select the ACTION keyword.

QueueName
The name of a message queue. FWDQ(' ') is not valid.

&DESTQ
Take the queue name from the *DestQName* field in the MQDLH structure.

&REPLYQ
Take the queue name from the *ReplyToQ* field in the message descriptor, MQMD.

You can specify REPLYQ (?*) in the message pattern to avoid error messages, when a rule specifying FWDQ (&REPLYQ) matches a message with a blank *ReplyToQ* field.

FWDQM (*QueueManagerName* **|&DESTQM|&REPLYQM|' ')**
The queue manager of the queue to which a message is forwarded.

QueueManagerName
The queue manager name for the queue to which the message is forwarded when you select the ACTION (FWD) keyword.

&DESTQM
Take the queue manager name from the *DestQMgrName* field in the MQDLH structure.

&REPLYQM
Take the queue manager name from the *ReplyToQMgr* field in the message descriptor, MQMD.

' ' FWDQM(' '), which is the default value, identifies the local queue manager.

HEADER (**YES** **|NO)**
Whether the MQDLH should remain on a message for which ACTION (FWD) is requested. By default, the MQDLH remains on the message. The HEADER keyword is not valid for actions other than FWD.

PUTAUT (**DEF** **|CTX)**
The authority with which messages should be put by the DLQ handler:

DEF Puts messages with the authority of the DLQ handler itself.

CTX Causes the messages to be put with the authority of the user ID in the message context. You must be authorized to assume the identity of other users, if you specify PUTAUT (CTX).

RETRY (*RetryCount* **|** **1** **)**
The number of times, in the range 1 - 999,999,999, to attempt an action (at the interval specified on the RETRYINT keyword of the control data).

Note: The count of attempts made by the DLQ handler to implement any particular rule is specific to the current instance of the DLQ handler; the count does not persist across restarts. If you restart the DLQ handler, the count of attempts made to apply a rule is reset to zero.

Rules table conventions:

The rules table must adhere to the following conventions regarding its syntax, structure, and contents.

- A rules table must contain at least one rule.
- Keywords can occur in any order.
- A keyword can be included once only in any rule.
- Keywords are not case sensitive.
- A keyword and its parameter value must be separated from other keywords by at least one blank or comma.
- Any number of blanks can occur at the beginning or end of a rule, and between keywords, punctuation, and values.
- Each rule must begin on a new line.
- For portability, the significant length of a line must not be greater than 72 characters.
- Use the plus sign (+) as the last non-blank character on a line to indicate that the rule continues from the first non-blank character in the next line. Use the minus sign (-) as the last non-blank character on a line to indicate that the rule continues from the start of the next line. Continuation characters can occur within keywords and parameters.

  For example:

```
APPLNAME('ABC+
D')
```

results in 'ABCD'.

```
APPLNAME('ABC-
D')
```

results in 'ABC D'.

- Comment lines, which begin with an asterisk (*), can occur anywhere in the rules table.
- Blank lines are ignored.
- Each entry in the DLQ handler rules table comprises one or more keywords and their associated parameters. The parameters must follow these syntax rules:
  - Each parameter value must include at least one significant character. The delimiting quotation marks in values enclosed in quotation marks are not considered significant. For example, these parameters are valid:

`FORMAT('ABC')`	3 significant characters
`FORMAT(ABC)`	3 significant characters
`FORMAT('A')`	1 significant character
`FORMAT(A)`	1 significant character
`FORMAT(' ')`	1 significant character

These parameters are invalid because they contain no significant characters:

```
FORMAT('')
FORMAT( )
FORMAT()
FORMAT
```

  - Wildcard characters are supported. You can use the question mark (?) in place of any single character, except a trailing blank. You can use the asterisk (*) in place of zero or more adjacent characters. The asterisk (*) and the question mark (?) are ***always*** interpreted as wildcard characters in parameter values.
  - You cannot include wildcard characters in the parameters of these keywords: ACTION, HEADER, RETRY, FWDQ, FWDQM, and PUTAUT.
  - Trailing blanks in parameter values, and in the corresponding fields in the message on the DLQ, are not significant when performing wildcard matches. However, leading and embedded blanks within strings in quotation marks are significant to wildcard matches.
  - Numeric parameters cannot include the question mark (?) wildcard character. You can include the asterisk (*) in place of an entire numeric parameter, but the asterisk cannot be included as part of a numeric parameter. For example, these are valid numeric parameters:

`MSGTYPE(2)`	Only reply messages are eligible
`MSGTYPE(*)`	Any message type is eligible
`MSGTYPE('*')`	Any message type is eligible

However, `MSGTYPE('2*')` is not valid, because it includes an asterisk (*) as part of a numeric parameter.

  - Numeric parameters must be in the range 0-999 999 999. If the parameter value is in this range, it is accepted, even if it is not currently valid in the field to which the keyword relates. You can use symbolic names for numeric parameters.
  - If a string value is shorter than the field in the MQDLH or MQMD to which the keyword relates, the value is padded with blanks to the length of the field. If the value, excluding asterisks, is longer than the field, an error is diagnosed. For example, these are all valid string values for an 8-character

field:

`'ABCDEFGH'`	8 characters
`'A*C*E*G*I'`	5 characters excluding asterisks
`'*A*C*E*G*I*K*M*O*'`	8 characters excluding asterisks

– Strings that contain blanks, lowercase characters, or special characters other than period (.), forward slash (?), underscore (_), and percent sign (%) must be enclosed in single quotation marks. Lowercase characters not enclosed in quotation marks are folded to uppercase. If the string includes a quotation mark, two single quotation marks must be used to denote both the beginning and the end of the quotation. When the length of the string is calculated, each occurrence of double quotation marks is counted as a single character.

Processing the rules table:

The DLQ handler searches the rules table for a rule with a pattern that matches a message on the DLQ.

The search begins with the first rule in the table, and continues sequentially through the table. When a rule with a matching pattern is found, the rules table attempts the action from that rule. The DLQ handler increments the retry count for a rule by 1 whenever it attempts to apply that rule. If the first attempt fails, the attempt is repeated until the count of attempts made matches the number specified on the RETRY keyword. If all attempts fail, the DLQ handler searches for the next matching rule in the table.

This process is repeated for subsequent matching rules until an action is successful. When each matching rule has been attempted the number of times specified on its RETRY keyword, and all attempts have failed, ACTION (IGNORE) is assumed. ACTION (IGNORE) is also assumed if no matching rule is found.

Note:

1. Matching rule patterns are sought only for messages on the DLQ that begin with an MQDLH. Messages that do not begin with an MQDLH are reported periodically as being in error, and remain on the DLQ indefinitely.
2. All pattern keywords can default, so that a rule can consist of an action only. Note, however, that action-only rules are applied to all messages on the queue that have MQDLHs and that have not already been processed in accordance with other rules in the table.
3. The rules table is validated when the DLQ handler starts, and errors flagged at that time. (Error messages issued by the DLQ handler are described in Reason codes.) You can make changes to the rules table at any time, but those changes do not come into effect until the DLQ handler is restarted.
4. The DLQ handler does not alter the content of messages, of the MQDLH, or of the message descriptor. The DLQ handler always puts messages to other queues with the message option MQPMO_PASS_ALL_CONTEXT.
5. Consecutive syntax errors in the rules table might not be recognized, because the validation of the rules table eliminates the generation of repetitive errors.
6. The DLQ handler opens the DLQ with the MQOO_INPUT_AS_Q_DEF option.
7. Multiple instances of the DLQ handler can run concurrently against the same queue, using the same rules table. However, it is more usual for there to be a one-to-one relationship between a DLQ and a DLQ handler.

Ensuring that all DLQ messages are processed:

The DLQ handler keeps a record of all messages on the DLQ that have been seen but not removed.

If you use the DLQ handler as a filter to extract a small subset of the messages from the DLQ, the DLQ handler still keeps a record of those messages on the DLQ that it did not process. Also, the DLQ handler cannot guarantee that new messages arriving on the DLQ will be seen, even if the DLQ is defined as first-in first-out (FIFO). If the queue is not empty, the DLQ is periodically re-scanned to check all messages.

For these reasons, try to ensure that the DLQ contains as few messages as possible. If messages that cannot be discarded or forwarded to other queues (for whatever reason) are allowed to accumulate on the queue, the workload of the DLQ handler increases and the DLQ itself is in danger of filling up.

You can take specific measures to enable the DLQ handler to empty the DLQ. For example, try not to use ACTION (IGNORE), which leaves messages on the DLQ. (Remember that ACTION (IGNORE) is assumed for messages that are not explicitly addressed by other rules in the table.) Instead, for those messages that you would otherwise ignore, use an action that moves the messages to another queue. For example:

```
ACTION (FWD) FWDQ (IGNORED.DEAD.QUEUE) HEADER (YES)
```

Similarly, make the final rule in the table a catchall to process messages that have not been addressed by earlier rules in the table. For example, the final rule in the table could be something like this:

```
ACTION (FWD) FWDQ (REALLY.DEAD.QUEUE) HEADER (YES)
```

This causes messages that fall through to the final rule in the table to be forwarded to the queue `REALLY.DEAD.QUEUE`, where they can be processed manually. If you do not have such a rule, messages are likely to remain on the DLQ indefinitely.

An example DLQ handler rules table:

Here is an example rules table that contains a single control-data entry and several rules:

```
************************************************************************
*    An example rules table for the STRMQMDLQ command       *
************************************************************************
* Control data entry
* ------------------
* If no queue manager name is supplied as an explicit parameter to
* STRMQMDLQ, use the default queue manager for the machine.
* If no queue name is supplied as an explicit parameter to STRMQMDLQ,
* use the DLQ defined for the local queue manager.
*
inputqm(' ') inputq(' ')

* Rules
* -----
* We include rules with ACTION (RETRY) first to try to
* deliver the message to the intended destination.

* If a message is placed on the DLQ because its destination
* queue is full, attempt to forward the message to its
* destination queue. Make 5 attempts at approximately
* 60-second intervals (the default value for RETRYINT).

REASON(MQRC_Q_FULL) ACTION(RETRY) RETRY(5)

* If a message is placed on the DLQ because of a put inhibited
* condition, attempt to forward the message to its
* destination queue. Make 5 attempts at approximately
* 60-second intervals (the default value for RETRYINT).

REASON(MQRC_PUT_INHIBITED) ACTION(RETRY) RETRY(5)

* The AAAA corporation is always sending messages with incorrect
* addresses. When we find a request from the AAAA corporation,
* we return it to the DLQ (DEADQ) of the reply-to queue manager
* (&REPLYQM).
* The AAAA DLQ handler attempts to redirect the message.

MSGTYPE(MQMT_REQUEST) REPLYQM(AAAA.*) +
ACTION(FWD) FWDQ(DEADQ) FWDQM(&REPLYQM)

* The BBBB corporation never does things by half measures. If
* the queue manager BBBB.1 is unavailable, try to
* send the message to BBBB.2

DESTQM(bbbb.1) +
action(fwd) fwdq(&DESTQ) fwdqm(bbbb.2) header(no)

* The CCCC corporation considers itself very security
* conscious, and believes that none of its messages
* will ever end up on one of our DLQs.
* Whenever we see a message from a CCCC queue manager on our
* DLQ, we send it to a special destination in the CCCC organization
* where the problem is investigated.

REPLYQM(CCCC.*) +
ACTION(FWD) FWDQ(ALARM) FWDQM(CCCC.SYSTEM)

* Messages that are not persistent run the risk of being
* lost when a queue manager terminates. If an application
* is sending nonpersistent messages, it must be able
* to cope with the message being lost, so we can afford to
* discard the message.

PERSIST(MQPER_NOT_PERSISTENT) ACTION(DISCARD)

* For performance and efficiency reasons, we like to keep
* the number of messages on the DLQ small.
* If we receive a message that has not been processed by
* an earlier rule in the table, we assume that it
* requires manual intervention to resolve the problem.
* Some problems are best solved at the node where the
* problem was detected, and others are best solved where
* the message originated. We do not have the message origin,
* but we can use the REPLYQM to identify a node that has
* some interest in this message.
* Attempt to put the message onto a manual intervention
* queue at the appropriate node. If this fails,
* put the message on the manual intervention queue at
* this node.

REPLYQM('?*') +
ACTION(FWD) FWDQ(DEADQ.MANUAL.INTERVENTION) FWDQM(&REPLYQM)

ACTION(FWD) FWDQ(DEADQ.MANUAL.INTERVENTION)
```

Invoking the DLQ handler:

Invoke the DLQ handler using the **runmqdlq** command. You can name the DLQ you want to process and the queue manager you want to use in two ways.

The two ways are as follows:
- As parameters to **runmqdlq** from the command prompt. For example:
  ```
  runmqdlq ABC1.DEAD.LETTER.QUEUE ABC1.QUEUE.MANAGER <qrule.rul
  ```
- In the rules table. For example:
  ```
  INPUTQ(ABC1.DEAD.LETTER.QUEUE) INPUTQM(ABC1.QUEUE.MANAGER)
  ```

The examples apply to the DLQ called ABC1.DEAD.LETTER.QUEUE, owned by the queue manager ABC1.QUEUE.MANAGER.

If you do not specify the DLQ or the queue manager as shown, the default queue manager for the installation is used along with the DLQ belonging to that queue manager.

The **runmqdlq** command takes its input from `stdin` ; you associate the rules table with **runmqdlq** by redirecting `stdin` from the rules table.

To run the DLQ handler you must be authorized to access both the DLQ itself and any message queues to which messages on the DLQ are forwarded. For the DLQ handler to put messages on queues with the authority of the user ID in the message context, you must also be authorized to assume the identity of other users.

For more information about the **runmqdlq** command, see runmqdlq.

Dead-letter queues
Undelivered messages troubleshooting

The sample DLQ handler, amqsdlq:

In addition to the DLQ handler invoked using the **runmqdlq** command, IBM MQ provides the source of a sample DLQ handler, amqsdlq, with a function that is similar to that provided by **runmqdlq** .

You can customize amqsdlq to provide a DLQ handler that meets your requirements. For example, you might decide that you want a DLQ handler that can process messages without dead-letter headers. (Both the default DLQ handler and the sample, amqsdlq, process only those messages on the DLQ that begin with a dead-letter header, MQDLH. Messages that do not begin with an MQDLH are identified as being in error, and remain on the DLQ indefinitely.)

MQ_INSTALLATION_PATH represents the high-level directory in which IBM MQ is installed.

In IBM MQ for Windows, the source of amqsdlq is supplied in the directory:
```
MQ_INSTALLATION_PATH\tools\c\samples\dlq
```

and the compiled version is supplied in the directory:
```
MQ_INSTALLATION_PATH\tools\c\samples\bin
```

In IBM MQ for UNIX and Linux systems, the source of amqsdlq is supplied in the directory:

```
MQ_INSTALLATION_PATH/samp/dlq
```

and the compiled version is supplied in the directory:

```
MQ_INSTALLATION_PATH/samp/bin
```

The DLQ handler rules table:

The DLQ handler rules table defines how the DLQ handler is to process messages that arrive on the DLQ.

There are two types of entry in a rules table:
- The first entry in the table, which is optional, contains *control data*.
- All other entries in the table are *rules* for the DLQ handler to follow. Each rule consists of a *pattern* (a set of message characteristics) that a message is matched against, and an *action* to be taken when a message on the DLQ matches the specified pattern. There must be at least one rule in a rules table.

Each entry in the rules table comprises one or more keywords.
Related information:
Dead-letter queues
Undelivered messages troubleshooting

Control data:

This section describes the keywords that you can include in a control-data entry in a DLQ handler rules table.

Note:
- The vertical line (|) separates alternatives, only one of which can be specified.
- All keywords are optional.

INPUTQ (*QueueName* **|' ')**
The name of the DLQ you want to process:
1. Any INPUTQ value you supply as a parameter to the **runmqdlq** command overrides any INPUTQ value in the rules table.
2. If you do not specify an INPUTQ value as a parameter to the **runmqdlq** command, but you **do** specify a value in the rules table, the INPUTQ value in the rules table is used.
3. If no DLQ is specified or you specify INPUTQ(' ') in the rules table, the name of the DLQ belonging to the queue manager with the name that is supplied as a parameter to the **runmqdlq** command is used.
4. If you do not specify an INPUTQ value as a parameter to the **runmqdlq** command or as a value in the rules table, the DLQ belonging to the queue manager named on the INPUTQM keyword in the rules table is used.

INPUTQM (*QueueManagerName* **|' ')**
The name of the queue manager that owns the DLQ named on the INPUTQ keyword:
1. Any INPUTQM value you supply as a parameter to the **runmqdlq** command overrides any INPUTQM value in the rules table.
2. If you do not specify an INPUTQM value as a parameter to the **runmqdlq** command, the INPUTQM value in the rules table is used.
3. If no queue manager is specified or you specify INPUTQM(' ') in the rules table, the default queue manager for the installation is used.

RETRYINT (*Interval* **|** **<u>60</u>** **)**
The interval, in seconds, at which the DLQ handler should reprocess messages on the DLQ that could not be processed at the first attempt, and for which repeated attempts have been requested. By default, the retry interval is 60 seconds.

WAIT (YES |NO| *nnn*)
Whether the DLQ handler should wait for further messages to arrive on the DLQ when it detects that there are no further messages that it can process.

YES The DLQ handler waits indefinitely.

NO The DLQ handler ends when it detects that the DLQ is either empty or contains no messages that it can process.

nnn The DLQ handler waits for *nnn* seconds for new work to arrive before ending, after it detects that the queue is either empty or contains no messages that it can process.

Specify WAIT (YES) for busy DLQs, and WAIT (NO) or WAIT (*nnn*) for DLQs that have a low level of activity. If the DLQ handler is allowed to terminate, invoke it again using triggering. For more information about triggering, see Starting IBM MQ applications using triggers.

An alternative to including control data in the rules table is to supply the names of the DLQ and its queue manager as input parameters to the **runmqdlq** command. If you specify a value both in the rules table and as input to the **runmqdlq** command, the value specified on the **runmqdlq** command takes precedence.

If you include a control-data entry in the rules table, it must be the **first** entry in the table.

Rules (patterns and actions):

A description of the pattern-matching keywords (those against which messages on the DLQ are matched), and the action keywords (those that determine how the DLQ handler is to process a matching message). An example rule is also provided.

The pattern-matching keywords

The pattern-matching keywords, which you use to specify values against which messages on the DLQ are matched, are as follows. (All pattern-matching keywords are optional):

APPLIDAT (*ApplIdentityData* | *)
The *ApplIdentityData* value specified in the message descriptor, MQMD, of the message on the DLQ.

APPLNAME (*PutApplName* | *)
The name of the application that issued the **MQPUT** or **MQPUT1** call, as specified in the *PutApplName* field of the message descriptor, MQMD, of the message on the DLQ.

APPLTYPE (*PutApplType* | *)
The *PutApplType* value, specified in the message descriptor, MQMD, of the message on the DLQ.

DESTQ (*QueueName* | *)
The name of the message queue for which the message is destined.

DESTQM (*QueueManagerName* | *)
The name of the queue manager of the message queue for which the message is destined.

FEEDBACK (*Feedback* | *)
When the *MsgType* value is MQFB_REPORT, *Feedback* describes the nature of the report.

You can use symbolic names. For example, you can use the symbolic name MQFB_COA to identify those messages on the DLQ that need confirmation of their arrival on their destination queues.

FORMAT (*Format* | *)
The name that the sender of the message uses to describe the format of the message data.

MSGTYPE (*MsgType* | *)
The message type of the message on the DLQ.

You can use symbolic names. For example, you can use the symbolic name MQMT_REQUEST to identify those messages on the DLQ that need replies.

PERSIST (*Persistence* **|** <u>*</u> **)**
The persistence value of the message. (The persistence of a message determines whether it survives restarts of the queue manager.)

You can use symbolic names. For example, you can use the symbolic name MQPER_PERSISTENT to identify messages on the DLQ that are persistent.

REASON (*ReasonCode* **|** <u>*</u> **)**
The reason code that describes why the message was put to the DLQ.

You can use symbolic names. For example, you can use the symbolic name MQRC_Q_FULL to identify those messages placed on the DLQ because their destination queues were full.

REPLYQ (*QueueName* **|** <u>*</u> **)**
The name of the reply-to queue specified in the message descriptor, MQMD, of the message on the DLQ.

REPLYQM (*QueueManagerName* **|** <u>*</u> **)**
The name of the queue manager of the reply-to queue, as specified in the message descriptor, MQMD, of the message on the DLQ.

USERID (*UserIdentifier* **|** <u>*</u> **)**
The user ID of the user who originated the message on the DLQ, as specified in the message descriptor, MQMD, of the message on the DLQ.

The action keywords

The action keywords, used to describe how a matching message is to be processed, are as follows:

ACTION (DISCARD|IGNORE|RETRY|FWD)
The action to be taken for any message on the DLQ that matches the pattern defined in this rule.

DISCARD
Delete the message from the DLQ.

IGNORE
Leave the message on the DLQ.

RETRY
If the first attempt to put the message on its destination queue fails, try again. The RETRY keyword sets the number of tries made to implement an action. The RETRYINT keyword of the control data controls the interval between attempts.

FWD Forward the message to the queue named on the FWDQ keyword.

You must specify the ACTION keyword.

FWDQ (*QueueName* **|&DESTQ|&REPLYQ)**
The name of the message queue to which to forward the message when ACTION (FWD) is requested.

QueueName
The name of a message queue. FWDQ(' ') is not valid.

&DESTQ
Take the queue name from the *DestQName* field in the MQDLH structure.

&REPLYQ
Take the queue name from the *ReplyToQ* field in the message descriptor, MQMD.

To avoid error messages when a rule specifying FWDQ (&REPLYQ) matches a message with a blank *ReplyToQ* field, specify REPLYQ (?*) in the message pattern.

FWDQM (*QueueManagerName* **|&DESTQM|&REPLYQM|' ')**
The queue manager of the queue to which to forward a message.

QueueManagerName
The name of the queue manager of the queue to which to forward a message when ACTION (FWD) is requested.

&DESTQM
Take the queue manager name from the *DestQMgrName* field in the MQDLH structure.

&REPLYQM
Take the queue manager name from the *ReplyToQMgr* field in the message descriptor, MQMD.

' ' FWDQM(' '), which is the default value, identifies the local queue manager.

HEADER (**YES** **|NO)**
Whether the MQDLH should remain on a message for which ACTION (FWD) is requested. By default, the MQDLH remains on the message. The HEADER keyword is not valid for actions other than FWD.

PUTAUT (**DEF** **|CTX)**
The authority with which messages should be put by the DLQ handler:

DEF Put messages with the authority of the DLQ handler itself.

CTX Put the messages with the authority of the user ID in the message context. If you specify PUTAUT (CTX), you must be authorized to assume the identity of other users.

RETRY (*RetryCount* **|** **1** **)**
The number of times, in the range 1 - 999,999,999, to try an action (at the interval specified on the RETRYINT keyword of the control data). The count of attempts made by the DLQ handler to implement any particular rule is specific to the current instance of the DLQ handler; the count does not persist across restarts. If the DLQ handler is restarted, the count of attempts made to apply a rule is reset to zero.

Example rule

Here is an example rule from a DLQ handler rules table:

```
PERSIST(MQPER_PERSISTENT) REASON (MQRC_PUT_INHIBITED) +
ACTION (RETRY) RETRY (3)
```

This rule instructs the DLQ handler to make three attempts to deliver to its destination queue any persistent message that was put on the DLQ because **MQPUT** and **MQPUT1** were inhibited.

All keywords that you can use on a rule are described in the rest of this section. Note the following:
- The default value for a keyword, if any, is underlined. For most keywords, the default value is * (asterisk), which matches any value.
- The vertical line (|) separates alternatives, only one of which can be specified.
- All keywords except ACTION are optional.

Rules table conventions:

The syntax, structure and contents of the DLQ handler rules table must adhere to these conventions.

The rules table must adhere to the following conventions:
- A rules table must contain at least one rule.
- Keywords can occur in any order.
- A keyword can be included only once in any rule.
- Keywords are not case-sensitive.
- A keyword and its parameter value must be separated from other keywords by at least one blank or comma.
- There can be any number of blanks at the beginning or end of a rule, and between keywords, punctuation, and values.
- Each rule must begin on a new line.
- On Windows systems, the last rule in the table must end with a carriage return/line feed character. You can achieve this by ensuring that you press the Enter key at the end of the rule, so that the last line of the table is a blank line.
- For reasons of portability, the significant length of a line must not be greater than 72 characters.
- Use the plus sign (+) as the last nonblank character on a line to indicate that the rule continues from the first nonblank character in the next line. Use the minus sign (-) as the last nonblank character on a line to indicate that the rule continues from the start of the next line. Continuation characters can occur within keywords and parameters.

  For example:
  ```
  APPLNAME('ABC+
  D')
  ```
  results in 'ABCD', and
  ```
  APPLNAME('ABC-
  D')
  ```
  results in 'ABC D'.
- Comment lines, which begin with an asterisk (*), can occur anywhere in the rules table.
- Blank lines are ignored.
- Each entry in the DLQ handler rules table comprises one or more keywords and their associated parameters. The parameters must follow these syntax rules:
  - Each parameter value must include at least one significant character. The delimiting single quotation marks in values that are enclosed in quotation marks are not considered to be significant. For example, these parameters are valid:

`FORMAT('ABC')`	3 significant characters
`FORMAT(ABC)`	3 significant characters
`FORMAT('A')`	1 significant character
`FORMAT(A)`	1 significant character
`FORMAT(' ')`	1 significant character

    These parameters are invalid because they contain no significant characters:

```
FORMAT('')
FORMAT( )
FORMAT()
FORMAT
```

- Wildcard characters are supported. You can use the question mark (?) instead of any single character, except a trailing blank; you can use the asterisk (*) instead of zero or more adjacent characters. The asterisk (*) and the question mark (?) are ***always*** interpreted as wildcard characters in parameter values.
- Wildcard characters cannot be included in the parameters of these keywords: ACTION, HEADER, RETRY, FWDQ, FWDQM, and PUTAUT.
- Trailing blanks in parameter values, and in the corresponding fields in the message on the DLQ, are not significant when performing wildcard matches. However, leading and embedded blanks within strings that are enclosed in single quotation marks are significant to wildcard matches.
- Numeric parameters cannot include the question mark (?) wildcard character. You can use the asterisk (*) instead of an entire numeric parameter, but not as part of a numeric parameter. For example, these are valid numeric parameters:

`MSGTYPE(2)`	Only reply messages are eligible
`MSGTYPE(*)`	Any message type is eligible
`MSGTYPE('*')`	Any message type is eligible

  However, `MSGTYPE('2*')` is not valid, because it includes an asterisk (*) as part of a numeric parameter.
- Numeric parameters must be in the range 0-999 999 999. If the parameter value is in this range, it is accepted, even if it is not currently valid in the field to which the keyword relates. You can use symbolic names for numeric parameters.
- If a string value is shorter than the field in the MQDLH or MQMD to which the keyword relates, the value is padded with blanks to the length of the field. If the value, excluding asterisks, is longer than the field, an error is diagnosed. For example, these are all valid string values for an 8 character field:

`'ABCDEFGH'`	8 characters
`'A*C*E*G*I'`	5 characters excluding asterisks
`'*A*C*E*G*I*K*M*O*'`	8 characters excluding asterisks

- Enclose strings that contain blanks, lowercase characters, or special characters other than period (.), forward slash (?), underscore (_), and percent sign (%) in single quotation marks. Lowercase characters not enclosed in single quotation marks are folded to uppercase. If the string includes a quotation, use two single quotation marks to denote both the beginning and the end of the quotation. When the length of the string is calculated, each occurrence of double quotation marks is counted as a single character.

How the rules table is processed:

The DLQ handler searches the rules table for a rule where the pattern matches a message on the DLQ.

The search begins with the first rule in the table, and continues sequentially through the table. When the DLQ handler finds a rule with a matching pattern, it takes the action from that rule. The DLQ handler increments the retry count for a rule by 1 whenever it applies that rule. If the first try fails, the DLQ handler tries again until the number of tries matches the number specified on the RETRY keyword. If all attempts fail, the DLQ handler searches for the next matching rule in the table.

This process is repeated for subsequent matching rules until an action is successful. When each matching rule has been attempted the number of times specified on its RETRY keyword, and all attempts have failed, ACTION (IGNORE) is assumed. ACTION (IGNORE) is also assumed if no matching rule is found.

Note:

1. Matching rule patterns are sought only for messages on the DLQ that begin with an MQDLH. Messages that do not begin with an MQDLH are reported periodically as being in error, and remain on the DLQ indefinitely.
2. All pattern keywords can be allowed to default, such that a rule can consist of an action only. Note, however, that action-only rules are applied to all messages on the queue that have MQDLHs and that have not already been processed in accordance with other rules in the table.
3. The rules table is validated when the DLQ handler starts, and errors are flagged at that time. You can make changes to the rules table at any time, but those changes do not come into effect until the DLQ handler restarts.
4. The DLQ handler does not alter the content of messages, the MQDLH, or the message descriptor. The DLQ handler always puts messages to other queues with the message option MQPMO_PASS_ALL_CONTEXT.
5. Consecutive syntax errors in the rules table might not be recognized because the rules table is designed to eliminate the generation of repetitive errors during validation.
6. The DLQ handler opens the DLQ with the MQOO_INPUT_AS_Q_DEF option.
7. Multiple instances of the DLQ handler can run concurrently against the same queue, using the same rules table. However, it is more usual for there to be a one-to-one relationship between a DLQ and a DLQ handler.

Dead-letter queues

Undelivered messages troubleshooting

Ensuring that all DLQ messages are processed:

The DLQ handler keeps a record of all messages on the DLQ that have been seen but not removed.

If you use the DLQ handler as a filter to extract a small subset of the messages from the DLQ, the DLQ handler still has to keep a record of those messages on the DLQ that it did not process. Also, the DLQ handler cannot guarantee that new messages arriving on the DLQ are seen, even if the DLQ is defined as first-in-first-out (FIFO). If the queue is not empty, the DLQ is periodically re-scanned to check all messages.

For these reasons, try to ensure that the DLQ contains as few messages as possible; if messages that cannot be discarded or forwarded to other queues (for whatever reason) are allowed to accumulate on the queue, the workload of the DLQ handler increases and the DLQ itself can fill up.

You can take specific measures to enable the DLQ handler to empty the DLQ. For example, try not to use ACTION (IGNORE), which leaves messages on the DLQ. (Remember that ACTION (IGNORE) is assumed for messages that are not explicitly addressed by other rules in the table.) Instead, for those messages that you would otherwise ignore, use an action that moves the messages to another queue. For example:

```
ACTION (FWD) FWDQ (IGNORED.DEAD.QUEUE) HEADER (YES)
```

Similarly, make the final rule in the table a catchall to process messages that have not been addressed by earlier rules in the table. For example, the final rule in the table could be something like this:

```
ACTION (FWD) FWDQ (REALLY.DEAD.QUEUE) HEADER (YES)
```

This forwards messages that fall through to the final rule in the table to the queue `REALLY.DEAD.QUEUE`, where they can be processed manually. If you do not have such a rule, messages are likely to remain on the DLQ indefinitely.

Dead-letter queues

Undelivered messages troubleshooting

Working with model queues

A queue manager creates a *dynamic queue* if it receives an MQI call from an application specifying a queue name that has been defined as a model queue. The name of the new dynamic queue is generated by the queue manager when the queue is created. A *model queue* is a template that specifies the attributes of any dynamic queues created from it. Model queues provide a convenient method for applications to create queues as required.

Defining a model queue

You define a model queue with a set of attributes in the same way that you define a local queue. Model queues and local queues have the same set of attributes, except that on model queues you can specify whether the dynamic queues created are temporary or permanent. (Permanent queues are maintained across queue manager restarts, temporary ones are not.) For example:

```
DEFINE QMODEL (GREEN.MODEL.QUEUE) +
DESCR('Queue for messages from application X') +
PUT (DISABLED) +
GET (ENABLED) +
NOTRIGGER +
MSGDLVSQ (FIFO) +
MAXDEPTH (1000) +
MAXMSGL (2000) +
USAGE (NORMAL) +
DEFTYPE (PERMDYN)
```

This command creates a model queue definition. From the DEFTYPE attribute, you can see that the actual queues created from this template are permanent dynamic queues. Any attributes not specified are automatically copied from the SYSYTEM.DEFAULT.MODEL.QUEUE default queue.

You can use the LIKE and REPLACE attributes when you define model queues, in the same way that you use them with local queues.

Using other commands with model queues

You can use the appropriate MQSC commands to display or alter a model queue's attributes, or to delete the model queue object. For example:

Use the following command to display the model queue's attributes:

```
DISPLAY QUEUE (GREEN.MODEL.QUEUE)
```

Use the following command to alter the model to enable puts on any dynamic queue created from this model:

```
ALTER QMODEL (BLUE.MODEL.QUEUE) PUT(ENABLED)
```

Use the following command to delete this model queue:

```
DELETE QMODEL (RED.MODEL.QUEUE)
```

Working with administrative topics

Use MQSC commands to manage administrative topics.

See MQSC commands for detailed information about these commands.

Administrative topic objects

Defining an administrative topic

Use the MQSC command **DEFINE TOPIC** to create an administrative topic. When defining an administrative topic you can optionally set each topic attribute.

Any attribute of the topic that is not explicitly set is inherited from the default administrative topic, SYSTEM.DEFAULT.TOPIC, that was created when the system installation was installed.

For example, the **DEFINE TOPIC** command that follows, defines a topic called **ORANGE.TOPIC** with these characteristics:

- Resolves to the topic string ORANGE. For information about how topic strings can be used, see Combining topic strings.

- Any attribute that is set to ASPARENT uses the attribute as defined by the parent topic of this topic. This action is repeated up the topic tree as far as the root topic, SYSTEM.BASE.TOPIC is found. For more information, see Topic trees.

```
DEFINE TOPIC (ORANGE.TOPIC) +
TOPICSTR (ORANGE) +
DEFPRTY(ASPARENT) +
NPMSGDLV(ASPARENT)
```

Note:

- Except for the value of the topic string, all the attribute values shown are the default values. They are shown here only as an illustration. You can omit them if you are sure that the defaults are what you want or have not been changed. See also "Displaying administrative topic object attributes."
- If you already have an administrative topic on the same queue manager with the name ORANGE.TOPIC, this command fails. Use the REPLACE attribute if you want to overwrite the existing definition of a topic, but see also "Changing administrative topic attributes" on page 113

Displaying administrative topic object attributes

Use the MQSC command **DISPLAY TOPIC** to display an administrative topic object.

To display all topics, use:

```
DISPLAY TOPIC(ORANGE.TOPIC)
```

You can selectively display attributes by specifying them individually. For example:

```
DISPLAY TOPIC(ORANGE.TOPIC) +
TOPICSTR +
DEFPRTY +
NPMSGDLV
```

This command displays the three specified attributes as follows:

```
AMQ8633: Display topic details.
     TOPIC(ORANGE.TOPIC)                                    TYPE(LOCAL)
     TOPICSTR(ORANGE)                                          DEFPRTY(ASPARENT)
     NPMSGDLV(ASPARENT)
```

To display the topic ASPARENT values as they are used at Runtime use DISPLAY TPSTATUS. For example, use:

```
DISPLAY TPSTATUS(ORANGE) DEFPRTY NPMSGDLV
```

The command displays the following details:

```
AMQ8754: Display topic status details.
TOPICSTR(ORANGE)           DEFPRTY(0)
NPMSGDLV(ALLAVAIL)
```

When you define an administrative topic, it takes any attributes that you do not specify explicitly from the default administrative topic, which is called SYSTEM.DEFAULT.TOPIC. To see what these default attributes are, use the following command:

```
DISPLAY TOPIC (SYSTEM.DEFAULT.TOPIC)
```

Changing administrative topic attributes

You can change topic attributes in two ways, using either the **ALTER TOPIC** command or the **DEFINE TOPIC** command with the **REPLACE** attribute.

If, for example, you want to change the default priority of messages delivered to a topic called ORANGE.TOPIC, to be 5, use either of the following commands.

- Using the **ALTER** command:

  ```
  ALTER TOPIC(ORANGE.TOPIC) DEFPRTY(5)
  ```

  This command changes a single attribute, that of the default priority of message delivered to this topic to 5; all other attributes remain the same.
- Using the **DEFINE** command:

  ```
  DEFINE TOPIC(ORANGE.TOPIC) DEFPRTY(5) REPLACE
  ```

  This command changes the default priority of messages delivered to this topic. All the other attributes are given their default values.

If you alter the priority of messages sent to this topic, existing messages are not affected. Any new message, however, use the specified priority if not provided by the publishing application.

Copying an administrative topic definition

You can copy a topic definition using the LIKE attribute on the **DEFINE** command.

For example:

```
DEFINE TOPIC (MAGENTA.TOPIC) +
LIKE (ORANGE.TOPIC)
```

This command creates a topic, MAGENTA.TOPIC, with the same attributes as the original topic, ORANGE.TOPIC, rather than those of the system default administrative topic. Enter the name of the topic to be copied exactly as it was entered when you created the topic. If the name contains lowercase characters, enclose the name in single quotation marks.

You can also use this form of the **DEFINE** command to copy a topic definition, but make changes to the attributes of the original. For example:

```
DEFINE TOPIC(BLUE.TOPIC) +
TOPICSTR(BLUE) +
LIKE(ORANGE.TOPIC)
```

You can also copy the attributes of the topic BLUE.TOPIC to the topic GREEN.TOPIC and specify that when publications cannot be delivered to their correct subscriber queue they are not placed onto the dead-letter queue. For example:

```
DEFINE TOPIC(GREEN.TOPIC) +
TOPICSTR(GREEN) +
LIKE(BLUE.TOPIC) +
USEDLQ(NO)
```

Deleting an administrative topic definition

You can use the MQSC command **DELETE TOPIC** to delete an administrative topic.

```
DELETE TOPIC(ORANGE.TOPIC)
```

Applications will no longer be able to open the topic for publication or make new subscriptions using the object name, ORANGE.TOPIC. Publishing applications that have the topic open are able to continue publishing the resolved topic string. Any subscriptions already made to this topic continue receiving publications after the topic has been deleted.

Applications that are not referencing this topic object but are using the resolved topic string that this topic object represented, 'ORANGE' in this example, continue to work. In this case they inherit the properties from a topic object higher in the topic tree. For more information, see Topic trees.

Working with subscriptions

Use MQSC commands to manage subscriptions.

Subscriptions can be one of three types, defined in the **SUBTYPE** attribute:

ADMIN
Administratively defined by a user.

PROXY
An internally created subscription for routing publications between queue managers.

API Created programmatically, for example, using the MQI MQSUB call.

See MQSC commands for detailed information about these commands.

Related concepts:

"Defining an administrative subscription"
Use the MQSC command **DEFINE SUB** to create an administrative subscription. You can also use the default defined in the default local subscription definition. Or, you can modify the subscription characteristics from those of the default local subscription, SYSTEM.DEFAULT.SUB that was created when the system was installed.

"Displaying attributes of subscriptions" on page 115
You can use the **DISPLAY SUB** command to display configured attributes of any subscription known to the queue manager.

"Changing local subscription attributes" on page 116
You can change subscription attributes in two ways, using either the **ALTER SUB** command or the **DEFINE SUB** command with the **REPLACE** attribute.

"Copying a local subscription definition" on page 116
You can copy a subscription definition using the **LIKE** attribute on the **DEFINE** command.

"Deleting a subscription" on page 117
You can use the MQSC command **DELETE SUB** to delete a local subscription.

Defining an administrative subscription

Use the MQSC command **DEFINE SUB** to create an administrative subscription. You can also use the default defined in the default local subscription definition. Or, you can modify the subscription characteristics from those of the default local subscription, SYSTEM.DEFAULT.SUB that was created when the system was installed.

For example, the **DEFINE SUB** command that follows defines a subscription called ORANGE with these characteristics:

- Durable subscription, meaning that it persists over queue manager restart, with unlimited expiry.
- Receive publications made on the ORANGE topic string, with the message priorities as set by the publishing applications.

- Publications delivered for this subscription are sent to the local queue SUBQ, this queue must be defined before the definition of the subscription.

```
DEFINE SUB (ORANGE) +
TOPICSTR (ORANGE) +
DESTCLAS (PROVIDED) +
DEST (SUBQ) +
EXPIRY (UNLIMITED) +
PUBPRTY (ASPUB)
```

Note:

- The subscription and topic string name do not have to match.
- Except for the values of the destination and topic string, all the attribute values shown are the default values. They are shown here only as an illustration. You can omit them if you are sure that the defaults are what you want or have not been changed. See also “Displaying attributes of subscriptions.”
- If you already have a local subscription on the same queue manager with the name ORANGE, this command fails. Use the **REPLACE** attribute if you want to overwrite the existing definition of a queue, but see also “Changing local subscription attributes” on page 116.
- If the queue SUBQ does not exist, this command fails.

Displaying attributes of subscriptions

You can use the **DISPLAY SUB** command to display configured attributes of any subscription known to the queue manager.

For example, use:

```
DISPLAY SUB (ORANGE)
```

You can selectively display attributes by specifying them individually. For example:

```
DISPLAY SUB (ORANGE) +
SUBID +
TOPICSTR +
DURABLE
```

This command displays the three specified attributes as follows:

```
AMQ8096: IBM MQ subscription inquired.
     SUBID(414D5120414141202020202020202020EE921E4E20002A03)
     SUB(ORANGE)                                                          TOPICSTR(ORANGE)
     DURABLE(YES)
```

TOPICSTR is the resolved topic string on which this subscriber is operating. When a subscription is defined to use a topic object the topic string from that object is used as a prefix to the topic string provided when making the subscription. SUBID is a unique identifier assigned by the queue manager when a subscription is created. This is a useful attribute to display because some subscription names might be long or in a different character sets for which it might become impractical.

An alternate method for displaying subscriptions is to use the SUBID:

```
DISPLAY SUB +
SUBID(414D5120414141202020202020202020EE921E4E20002A03) +
TOPICSTR +
DURABLE
```

This command gives the same output as before:

```
AMQ8096: IBM MQ subscription inquired.
SUBID(414D5120414141202020202020202020EE921E4E20002A03)
     SUB(ORANGE)                                                          TOPICSTR(ORANGE)
     DURABLE(YES)
```

Proxy subscriptions on a queue manager are not displayed by default. To display them specify a **SUBTYPE** of PROXY or ALL.

You can use the DISPLAY SBSTATUS command to display the Runtime attributes. For example, use the command:

```
DISPLAY SBSTATUS(ORANGE) NUMMSGS
```

The following output is displayed:

```
AMQ8099: IBM MQ subscription status inquired.
SUB(ORANGE)
SUBID(414D5120414141202020202020202020EE921E4E20002A03)
NUMMSGS(0)
```

When you define an administrative subscription, it takes any attributes that you do not specify explicitly from the default subscription, which is called SYSTEM.DEFAULT.SUB. To see what these default attributes are, use the following command:

```
DISPLAY SUB (SYSTEM.DEFAULT.SUB)
```

Changing local subscription attributes

You can change subscription attributes in two ways, using either the **ALTER SUB** command or the **DEFINE SUB** command with the **REPLACE** attribute.

If, for example, you want to change the priority of messages delivered to a subscription called ORANGE to be 5, use either of the following commands:

- Using the ALTER command:
  ```
  ALTER SUB(ORANGE) PUBPRTY(5)
  ```
  This command changes a single attribute, that of the priority of messages delivered to this subscription to 5; all other attributes remain the same.
- Using the DEFINE command:
  ```
  DEFINE SUB (ORANGE) PUBPRTY(5) REPLACE
  ```
  This command changes not only the priority of messages delivered to this subscription, but all the other attributes which are given their default values.

If you alter the priority of messages sent to this subscription, existing messages are not affected. Any new messages, however, are of the specified priority.

Copying a local subscription definition

You can copy a subscription definition using the **LIKE** attribute on the **DEFINE** command.

For example:

```
DEFINE SUB (BLUE) +
LIKE (ORANGE)
```

You can also copy the attributes of the sub REAL to the sub THIRD.SUB, and specify that the correlID of delivered publications is THIRD, rather than the publishers correlID. For example:

```
DEFINE SUB(THIRD.SUB) +
LIKE(BLUE) +
DESTCORL(ORANGE)
```

Deleting a subscription

You can use the MQSC command **DELETE SUB** to delete a local subscription.

```
DELETE SUB(ORANGE)
```

You can also delete a subscription using the SUBID:

```
DELETE SUB SUBID(414D5120414141202020202020202020EE921E4E20002A03)
```

Checking messages on a subscription

About this task

When a subscription is defined it is associated with a queue. Published messages matching this subscription are put to this queue.

Note that the following **runmqsc** commands show only those subscriptions that received messages.

To check for messages currently queued for a subscription perform the following steps:

Procedure

1. To check for messages queued for a subscription type **DISPLAY SBSTATUS(<sub_name>) NUMMSGS**, see "Displaying attributes of subscriptions" on page 115.
2. If the **NUMMSGS** value is greater than zero identify the queue associated with the subscription by typing **DISPLAY SUB(<sub_name>)DEST**.
3. Using the name of the queue returned you can view the messages by following the technique described in "Browsing queues" on page 87.

Working with services

Service objects are a means by which additional processes can be managed as part of a queue manager. With services, you can define programs that are started and stopped when the queue manager starts and ends. IBM MQ services are always started under the user ID of the user who started the queue manager.

Service objects can be either of the following types:

Server A server is a service object that has the parameter SERVTYPE specified as SERVER. A server service object is the definition of a program that is executed when a specified queue manager is started. Server service objects define programs that typically run for a long time. For example, a server service object can be used to execute a trigger monitor process, such as **runmqtrm** .

Only one instance of a server service object can run concurrently. The status of running server service objects can be monitored using the MQSC command, DISPLAY SVSTATUS.

Command

A command is a service object that has the parameter SERVTYPE specified as COMMAND. Command service objects are similar to server service objects, however multiple instances of a command service object can run concurrently, and their status cannot be monitored using the MQSC command DISPLAY SVSTATUS.

If the MQSC command, STOP SERVICE, is executed no check is made to determine whether the program started by the MQSC command, START SERVICE, is still active before executing the stop program.

Defining a service object

You define a service object with various attributes.

The attributes are as follows:

SERVTYPE
Defines the type of the service object. Possible values are as follows:

SERVER
A server service object.

Only one instance of a server service object can be executed at a time. The status of server service objects can be monitored using the MQSC command, DISPLAY SVSTATUS.

COMMAND
A command service object.

Multiple instances of a command service object can be executed concurrently. The status of a command service objects cannot be monitored.

STARTCMD
The program that is executed to start the service. A fully qualified path to the program must be specified.

STARTARG
Arguments passed to the start program.

STDERR
Specifies the path to a file to which the standard error (stderr) of the service program should be redirected.

STDOUT
Specifies the path to a file to which the standard output (stdout) of the service program should be redirected.

STOPCMD
The program that is executed to stop the service. A fully qualified path to the program must be specified.

STOPARG
Arguments passed to the stop program.

CONTROL
Specifies how the service is to be started and stopped:

MANUAL
The service is not to be started automatically or stopped automatically. It is controlled by use of the START SERVICE and STOP SERVICE commands. This is the default value.

QMGR
The service being defined is to be started and stopped at the same time as the queue manager is started and stopped.

STARTONLY
The service is to be started at the same time as the queue manager is started, but is not requested to stop when the queue manager is stopped.

Related concepts:

"Managing services"
By using the CONTROL parameter, an instance of a service object can be either started and stopped automatically by the queue manager, or started and stopped using the MQSC commands START SERVICE and STOP SERVICE.

Managing services

By using the CONTROL parameter, an instance of a service object can be either started and stopped automatically by the queue manager, or started and stopped using the MQSC commands START SERVICE and STOP SERVICE.

When an instance of a service object is started, a message is written to the queue manager error log containing the name of the service object and the process ID of the started process. An example log entry for a server service object starting follows:

```
02/15/2005 11:54:24 AM - Process(10363.1) User(mqm) Program(amqzmgr0)
Host(HOST_1) Installation(Installation1)
VRMF(7.1.0.0) QMgr(A.B.C)
AMQ5028: The Server 'S1' has started. ProcessId(13031).

EXPLANATION:
The Server process has started.
ACTION:
None.
```

An example log entry for a command service object starting follows:

```
02/15/2005 11:53:55 AM - Process(10363.1) User(mqm) Program(amqzmgr0)
Host(HOST_1) Installation(Installation1)
VRMF(7.1.0.0) QMgr(A.B.C)
AMQ5030: The Command 'C1' has started. ProcessId(13030).

EXPLANATION:
The Command has started.
ACTION:
None.
```

When an instance server service stops, a message is written to the queue manager error logs containing the name of the service and the process ID of the ending process. An example log entry for a server service object stopping follows:

```
02/15/2005 11:54:54 AM - Process(10363.1) User(mqm) Program(amqzmgr0)
Host(HOST_1) Installation(Installation1)
VRMF(7.1.0.0) QMgr(A.B.C)
AMQ5029: The Server 'S1' has ended. ProcessId(13031).

EXPLANATION:
The Server process has ended.
ACTION:
None.
```

"Additional environment variables"
When a service is started, the environment in which the service process is started is inherited from the environment of the queue manager. It is possible to define additional environment variables to be set in the environment of the service process by adding the variables you want to define to one of the `service.env` environment override files.

Additional environment variables

When a service is started, the environment in which the service process is started is inherited from the environment of the queue manager. It is possible to define additional environment variables to be set in the environment of the service process by adding the variables you want to define to one of the `service.env` environment override files.

Note:

There are two possible files to which you can add environment variables:

- The machine scope `service.env` file, which is located in `/var/mqm` on UNIX and Linux systems, or in the data directory selected during installation on Windows systems.
- The queue manager scope `service.env` file, which is located in the queue manager data directory. For example, the location of the environment override file for a queue manager named `QMNAME` is:
  - On UNIX and Linux systems, `/var/mqm/qmgrs/QMNAME/service.env`
  - On Windows systems, `C:\ProgramData\IBM\MQ\qmgrs\QMNAME\service.env`

Both files are processed, if available, with definitions in the queue manager scope file taking precedence over those definitions in the machine scope file.

Any environment variable can be specified in `service.env`. For example, if the IBM MQ service runs a number of commands, it might be useful to set the PATH user variable in the `service.env` file. The values that you set the variable to can't be environment variables; for example CLASSPATH= *%CLASSPATH%* is incorrect. Similarly, on Linux PATH= *$PATH* `:/opt/mqm/bin` would give unexpected results.

CLASSPATH must be capitalized, and the class path statement can contain only literals. Some services (Telemetry for example) set their own class path. The CLASSPATH defined in `service.env` is added to it.

The format of the variables defined in the file, `service.env` is a list of name and value variable pairs. Each variable must be defined on a new line, and each variable is taken as it is explicitly defined, including white space. An example of the file, `service.env` follows:

```
#********************************************************************#
#*                                                                  *#
#* <N_OCO_COPYRIGHT>                                                *#
#* Licensed Materials - Property of IBM                             *#
#*                                                                  *#
#* 63H9336                                                          *#

"Replaceable inserts on service definitions"
In the definition of a service object, it is possible to substitute tokens. Tokens that are substituted are automatically replaced with their expanded text when the service program is executed. Substitute tokens can be taken from the following list of common tokens, or from any variables that are defined in the file, service.env.

Replaceable inserts on service definitions

In the definition of a service object, it is possible to substitute tokens. Tokens that are substituted are automatically replaced with their expanded text when the service program is executed. Substitute tokens can be taken from the following list of common tokens, or from any variables that are defined in the file, service.env.

The following are common tokens that can be used to substitute tokens in the definition of a service object:

MQ_INSTALL_PATH
The location where IBM MQ is installed.

MQ_DATA_PATH
The location of the IBM MQ data directory:

- On UNIX and Linux systems, the IBM MQ data directory location is `/var/mqm/`
- On Windows systems, the location of the IBM MQ data directory is the data directory selected during the installation of IBM MQ

QMNAME
The current queue manager name.

MQ_SERVICE_NAME
The name of the service.

MQ_SERVER_PID
This token can only be used by the STOPARG and STOPCMD arguments.

For server service objects this token is replaced with the process id of the process started by the STARTCMD and STARTARG arguments. Otherwise, this token is replaced with 0.

MQ_Q_MGR_DATA_PATH
The location of the queue manager data directory.

MQ_Q_MGR_DATA_NAME
The transformed name of the queue manager. For more information on name transformation, see Understanding IBM MQ file names.

To use replaceable inserts, insert the token within + characters into any of the STARTCMD, STARTARG, STOPCMD, STOPARG, STDOUT or STDERR strings. For examples of this, see "Examples on using service objects" on page 122.

Examples on using service objects

The services in this section are written with UNIX style path separator characters, except where otherwise stated.

Using a server service object:

This example shows how to define, use, and alter, a server service object to start a trigger monitor.

1. A server service object is defined, using the following MQSC command:

   ```
   DEFINE SERVICE(S1) +
   CONTROL(QMGR) +
   SERVTYPE(SERVER) +
   STARTCMD('+MQ_INSTALL_PATH+bin/runmqtrm') +
   STARTARG('-m +QMNAME+ -q ACCOUNTS.INITIATION.QUEUE') +
   STOPCMD('+MQ_INSTALL_PATH+bin/amqsstop') +
   STOPARG('-m +QMNAME+ -p +MQ_SERVER_PID+')
   ```

   Where:

   `+MQ_INSTALL_PATH+` is a token representing the installation directory.

   `+QMNAME+` is a token representing the name of the queue manager.

   `ACCOUNTS.INITIATION.QUEUE` is the initiation queue.

   `amqsstop` is a sample program provided with IBM MQ which requests the queue manager to break all connections for the process id. `amqsstop` generates PCF commands, therefore the command server must be running.

   `+MQ_SERVER_PID+` is a token representing the process id passed to the stop program.

   See "Replaceable inserts on service definitions" on page 121 for a list of the common tokens.

2. An instance of the server service object will execute when the queue manager is next started. However, we will start an instance of the server service object immediately with the following MQSC command:

   ```
   START SERVICE(S1)
   ```

3. The status of the server service process is displayed, using the following MQSC command:

   ```
   DISPLAY SVSTATUS(S1)
   ```

4. This example now shows how to alter the server service object and have the updates picked up by manually restarting the server service process. The server service object is altered so that the initiation queue is specified as `JUPITER.INITIATION.QUEUE`. The following MQSC command is used:

   ```
   ALTER SERVICE(S1) +
   STARTARG('-m +QMNAME+ -q JUPITER.INITIATION.QUEUE')
   ```

   Note: A running service will not pick up any updates to its service definition until it is restarted.

5. The server service process is restarted so that the alteration is picked up, using the following MQSC commands:

   ```
   STOP SERVICE(S1)
   ```

   Followed by:

   ```
   START SERVICE(S1)
   ```

   The server service process is restarted and picks up the alterations made in 4.

   Note: The MQSC command, `STOP SERVICE`, can only be used if a STOPCMD argument is specified in the service definition.

Using a command service object:

This example shows how to define a command service object to start a program that writes entries to the operating system's system log when a queue manager is started or stopped.

1. The command service object is defined, using the following MQSC command:

   ```
   DEFINE SERVICE(S2) +
   CONTROL(QMGR) +
   SERVTYPE(COMMAND) +
   STARTCMD('/usr/bin/logger') +
   STARTARG('Queue manager +QMNAME+ starting') +
   STOPCMD('/usr/bin/logger') +
   STOPARG('Queue manager +QMNAME+ stopping')
   ```

   Where:

   `logger` is the UNIX and Linux system supplied command to write to the system log.

   `+QMNAME+` is a token representing the name of the queue manager.

Using a command service object when a queue manager ends only:

This example shows how to define a command service object to start a program that writes entries to the operating system's system log when a queue manager is stopped only.

1. The command service object is defined, using the following MQSC command:

   ```
   DEFINE SERVICE(S3) +
   CONTROL(QMGR) +
   SERVTYPE(COMMAND) +
   STOPCMD('/usr/bin/logger') +
   STOPARG('Queue manager +QMNAME+ stopping')
   ```

   Where:

   `logger` is a sample program provided with IBM MQ that can write entries to the operating system's system log.

   `+QMNAME+` is a token representing the name of the queue manager.

More on passing arguments:

This example shows how to define a server service object to start a program called `runserv` when a queue manager is started.

This example is written with Windows style path separator characters.

One of the arguments that is to be passed to the starting program is a string containing a space. This argument needs to be passed as a single string. To achieve this, double quotation marks are used as shown in the following command to define the command service object:

1. The server service object is defined, using the following MQSC command:

   ```
   DEFINE SERVICE(S1) SERVTYPE(SERVER) CONTROL(QMGR) +
   STARTCMD('C:\Program Files\Tools\runserv.exe') +
   STARTARG('-m +QMNAME+ -d "C:\Program Files\Tools\"') +
   STDOUT('C:\Program Files\Tools\+MQ_SERVICE_NAME+.out')
   ```

   ```
   DEFINE SERVICE(S4) +
   CONTROL(QMGR) +
   SERVTYPE(SERVER) +
   STARTCMD('C:\Program Files\Tools\runserv.exe') +
   STARTARG('-m +QMNAME+ -d "C:\Program Files\Tools\"') +
   STDOUT('C:\Program Files\Tools\+MQ_SERVICE_NAME+.out')
   ```

Where:

+QMNAME+ is a token representing the name of the queue manager.

"C:\Program Files\Tools\" is a string containing a space, which will be passed as a single string.

Autostarting a Service:

This example shows how to define a server service object that can be used to automatically start the Trigger Monitor when the queue manager starts.

1. The server service object is defined, using the following MQSC command:

   ```
   DEFINE SERVICE(TRIG_MON_START) +
   CONTROL(QMGR) +
   SERVTYPE(SERVER) +
   STARTCMD('runmqtrm') +
   STARTARG('-m +QMNAME+ -q +IQNAME+')
   ```

   Where:

   +QMNAME+ is a token representing the name of the queue manager.

   +IQNAME+ is an environment variable defined by the user in one of the service.env files representing the name of the initiation queue.

Managing objects for triggering

IBM MQ enables you to start an application automatically when certain conditions on a queue are met. For example, you might want to start an application when the number of messages on a queue reaches a specified number. This facility is called *triggering*. You have to define the objects that support triggering.

Triggering described in detail in Starting IBM MQ applications using triggers.

Defining an application queue for triggering

An application queue is a local queue that is used by applications for messaging, through the MQI. Triggering requires a number of queue attributes to be defined on the application queue.

Triggering itself is enabled by the *Trigger* attribute (TRIGGER in MQSC commands). In this example, a trigger event is to be generated when there are 100 messages of priority 5 or greater on the local queue MOTOR.INSURANCE.QUEUE, as follows:

```
DEFINE QLOCAL (MOTOR.INSURANCE.QUEUE) +
PROCESS (MOTOR.INSURANCE.QUOTE.PROCESS) +
MAXMSGL (2000) +
DEFPSIST (YES) +
INITQ (MOTOR.INS.INIT.QUEUE) +
TRIGGER +
TRIGTYPE (DEPTH) +
TRIGDPTH (100)+
TRIGMPRI (5)
```

where:

QLOCAL (MOTOR.INSURANCE.QUEUE)
Is the name of the application queue being defined.

PROCESS (MOTOR.INSURANCE.QUOTE.PROCESS)
Is the name of the process definition that defines the application to be started by a trigger monitor program.

MAXMSGL (2000)
Is the maximum length of messages on the queue.

DEFPSIST (YES)
Specifies that messages on this queue are persistent by default.

INITQ (MOTOR.INS.INIT.QUEUE)
Is the name of the initiation queue on which the queue manager is to put the trigger message.

TRIGGER
Is the trigger attribute value.

TRIGTYPE (DEPTH)
Specifies that a trigger event is generated when the number of messages of the required priority (TRIGMPRI) reaches the number specified in TRIGDPTH.

TRIGDPTH (100)
Is the number of messages required to generate a trigger event.

TRIGMPRI (5)
Is the priority of messages that are to be counted by the queue manager in deciding whether to generate a trigger event. Only messages with priority 5 or higher are counted.

Defining an initiation queue

When a trigger event occurs, the queue manager puts a trigger message on the initiation queue specified in the application queue definition. Initiation queues have no special settings, but you can use the following definition of the local queue MOTOR.INS.INIT.QUEUE for guidance:

```
DEFINE QLOCAL(MOTOR.INS.INIT.QUEUE) +
GET (ENABLED) +
NOSHARE +
NOTRIGGER +
MAXMSGL (2000) +
MAXDEPTH (1000)
```

Defining a process

Use the DEFINE PROCESS command to create a process definition. A process definition defines the application to be used to process messages from the application queue. The application queue definition names the process to be used and thereby associates the application queue with the application to be used to process its messages. This is done through the PROCESS attribute on the application queue MOTOR.INSURANCE.QUEUE. The following MQSC command defines the required process, MOTOR.INSURANCE.QUOTE.PROCESS, identified in this example:

```
DEFINE PROCESS (MOTOR.INSURANCE.QUOTE.PROCESS) +
DESCR ('Insurance request message processing') +
APPLTYPE (UNIX) +
APPLICID ('/u/admin/test/IRMP01') +
USERDATA ('open, close, 235')
```

Where:

MOTOR.INSURANCE.QUOTE.PROCESS
Is the name of the process definition.

DESCR ('Insurance request message processing')
Describes the application program to which this definition relates. This text is displayed when you use the DISPLAY PROCESS command. This can help you to identify what the process does. If you use spaces in the string, you must enclose the string in single quotation marks.

APPLTYPE (UNIX)
Is the type of application to be started.

APPLICID ('/u/admin/test/IRMP01')
Is the name of the application executable file, specified as a fully qualified file name. In Windows systems, a typical `APPLICID` value would be `c:\appl\test\irmp01.exe`.

USERDATA ('open, close, 235')
Is user-defined data, which can be used by the application.

Displaying attributes of a process definition

Use the DISPLAY PROCESS command to examine the results of your definition. For example:

```
DISPLAY PROCESS (MOTOR.INSURANCE.QUOTE.PROCESS)

24 : DISPLAY PROCESS (MOTOR.INSURANCE.QUOTE.PROCESS) ALL
AMQ8407: Display Process details.
DESCR ('Insurance request message processing')
APPLICID ('/u/admin/test/IRMP01')
USERDATA (open, close, 235)
PROCESS (MOTOR.INSURANCE.QUOTE.PROCESS)
APPLTYPE (UNIX)
```

You can also use the MQSC command ALTER PROCESS to alter an existing process definition, and the DELETE PROCESS command to delete a process definition.

Using the `dmpmqmsg` utility between two systems

The **dmpmqmsg** utility (formerly *qload*) is incorporated into the product in Version 8.0. Formerly the utility has been available as SupportPac MO03.

Overview

The **dmpmqmsg** utility allows you to copy or move the contents of a queue, or its messages, to a file. This file can be saved away as required and used at some later point to reload the messages back onto the queue.

Important: The file has a specific format understood by the utility. However, the file is human-readable, so that you can update it in an editor before you reload it. If you do edit the file you must not change its format.

Possible uses are:
- Saving the messages that are on a queue, to a file. Possibly for archiving purposes, and later reload back to a queue.
- Reloading a queue with messages you previously saved to a file.
- Removing old messages from a queue.
- 'Replaying' test messages from a stored location, even maintaining the correct time between the messages if required.

Attention: SupportPac MO03 used the **-l** parameter for specifying local or client binding. **-l** has been replaced by the **-c** parameter.

-P is now used for codepage information instead of **-c**.

See dmpmqmsg for further information on the command and the available parameters.

Example of using the `dmpmqmsg` utility on Linux, using a Windows machine

You have a queue manager on a Linux machine that has messages on a queue (*Q1*) that you want to move into another queue (*Q2*) in the same queue manager. You want to initiate the **dmpmqmsg** utility from a Windows machine.

Queue (*Q1*) has four messages that have been added by using the sample **amqsput** (local queue manager) or **amqsputc** (remote queue manager) application.

On the Linux machine you see:

```
display ql(Q1) CURDEPTH
        2 : display ql(Q1) CURDEPTH
AMQ8409: Display Queue details.
     QUEUE(Q1)
TYPE(QLOCAL)
     CURDEPTH(4)
```

Set the MQSERVER environment variable to point to the queue manager in Linux. For example:

```
set MQSERVER=SYSTEM.DEF.SVRCONN/TCP/veracruz.x.com(1414)
```

where *veracruz* is the name of the machine.

Run the **dmpmqmsg** utility to read from the queue, *Q1*, and store the output in `c:\temp\mqqload.txt`.

Connect as a remote client to the queue manager, *QM_VER*, running in the Linux host and port established by MQSERVER. You achieve the connection as a remote client by using the attribute: `-c`.

```
dmpmqmsg -m QM_VER -i Q1 -f c:\temp\mqqload.txt -c
Read      - Files:    0   Messages:      4   Bytes:           22
Written - Files:    1   Messages:      4   Bytes:           22
```

The output file `c:\temp\mqqload.txt` contains text, using a format that the **dmpmqmsg** utility understands.

On the Windows machine, issue the **dmpmqmsg** command (using the `-o` option instead of the `-i` option) to load queue (*Q2*) on the Linux machine from a file on the Windows machine:

```
dmpmqmsg -m QM_VER -o Q2 -f c:\temp\mqqload.txt -c
Read      - Files:    1   Messages:      4   Bytes:           22
Written - Files:    0   Messages:      4   Bytes:           22
```

On the Linux machine, note that there are now four messages in the queue that have been restored from the file.

```
display ql(Q2) CURDEPTH
        6 : display ql(Q2) CURDEPTH
AMQ8409: Display Queue details.
     QUEUE(Q2)
TYPE(QLOCAL)
     CURDEPTH(4)
```

On the Linux machine,

Delete the messages from the original queue.

```
clear qlocal(Q1)
        4 : clear qlocal(Q1)
AMQ8022: IBM MQ queue cleared.
```

Confirm that there are no more messages on the original queue:

```
display ql(Q1) CURDEPTH
        5 : display ql(Q1) CURDEPTH
AMQ8409: Display Queue details.
     QUEUE(Q1)
TYPE(QLOCAL)
     CURDEPTH(0)
```

See dmpmqmsg for a description of the command and its parameters.

Related concepts:

"Examples of using the **dmpmqmsg** utility"
Simple ways in which you can use the **dmpmqmsg** utility (formerly *qload*). This utility is incorporated into the product in Version 8.0.

Examples of using the `dmpmqmsg` utility

Simple ways in which you can use the **dmpmqmsg** utility (formerly *qload*). This utility is incorporated into the product in Version 8.0.

Formerly the utility has been available as SupportPac MO03.

Unload a queue to a file

Use the following options on the command line to save the messages that are on a queue, into a file:

```
dmpmqmsg -m QM1 -i Q1 -f c:\myfile
```

This command takes a copy of the messages from the queue and saves them in the file specified.

Unload a queue to a series of files

You can unload a queue to a series of files by using an `insert` character in the file name. In this mode each message is written to a new file:

```
dmpmqmsg -m QM1 -i Q1 -f c:\myfile%n
```

This command unloads the queue to files, `myfile1`, `myfile2`, `myfile3`, and so on.

Load a queue from a file

To reload a queue with the messages you saved in "Unload a queue to a file," use the following options on the command line:

```
dmpmqmsg -m QM1 -o Q1 -f c:\myfile%n
```

This command unloads the queue to files, `myfile1`, `myfile2`, `myfile3`, and so on.

Load a queue from a series of files

You can load a queue from a series of files by using an `insert` character in the file name. In this mode each message is written to a new file:

```
dmpmqmsg -m QM1 -o Q1 -f c:\myfile%n
```

This command loads the queue to files, `myfile1`, `myfile2`, `myfile3`, and so on.

Copy the messages from one queue to another queue

Replace the file parameter in "Unload a queue to a file," with another queue name and use the following options:

```
dmpmqmsg -m QM1 -i Q1 -o Q2
```

This command allows the messages from one queue to be copied to another queue.

Copy the first 100 messages from one queue to another queue

Use the command in the previous example and add the `-r#10` option:

```
dmpmqmsg -m QM1 -i Q1 -o Q2 -r#10
```

Move the messages from one queue to another queue

A variation on "Load a queue from a file" on page 128. Note the distinction between using **-i** (lower case) which only browses a queue, and **-I** (upper case) which destructively gets from a queue:

```
dmpmqmsg -m QM1 -I Q1 -o Q2
```

Move messages older than one day from one queue to another queue

This example shows the use of age selection. Messages can be selected that are older than, younger than, or within a range of ages.

```
dmpmqmsg -m QM1 -I Q1 -o Q2 -T1440
```

Display the ages of messages currently on a queue

Use the following options on the command line:

```
dmpmqmsg -m QM1 -i Q1 -f stdout -dT
```

Work with the message file

Having unloaded the message from your queue, as in "Unload a queue to a file" on page 128, you might want to edit the file.

You might also want to change the format of the file to use one of the display options that you did not specify at the time you unloaded the queue.

You can use the **dmpmqmsg** utility to reprocess the file into the desired format even after the unload of the queue has taken place. Use the following options on the command line.

```
dmpmqmsg -f c:\oldfile -f c:\newfile -dA
```

See dmpmqmsg for a description of the command and its parameters.

Administering remote IBM MQ objects

This section tells you how to administer IBM MQ objects on a remote queue manager using MQSC commands, and how to use remote queue objects to control the destination of messages and reply messages.

This section describes:
- "Channels, clusters, and remote queuing" on page 130
- "Remote administration from a local queue manager" on page 131
- "Creating a local definition of a remote queue" on page 137
- "Using remote queue definitions as aliases" on page 142
- "Data conversion" on page 143

Channels, clusters, and remote queuing

A queue manager communicates with another queue manager by sending a message and, if required, receiving back a response. The receiving queue manager could be:

- On the same machine
- On another machine in the same location (or even on the other side of the world)
- Running on the same platform as the local queue manager
- Running on another platform supported by IBM MQ

These messages might originate from:

- User-written application programs that transfer data from one node to another
- User-written administration applications that use PCF commands or the MQAI
- The IBM MQ Explorer.
- Queue managers sending:
  - Instrumentation event messages to another queue manager
  - MQSC commands issued from a **runmqsc** command in indirect mode (where the commands are run on another queue manager)

Before a message can be sent to a remote queue manager, the local queue manager needs a mechanism to detect the arrival of messages and transport them consisting of:

- At least one channel
- A transmission queue
- A channel initiator

For a remote queue manager to received a message, a listener is required.

A channel is a one-way communication link between two queue managers and can carry messages destined for any number of queues at the remote queue manager.

Each end of the channel has a separate definition. For example, if one end is a sender or a server, the other end must be a receiver or a requester. A simple channel consists of a *sender channel definition* at the local queue manager end and a *receiver channel definition* at the remote queue manager end. The two definitions must have the same name and together constitute a single message channel.

If you want the remote queue manager to respond to messages sent by the local queue manager, set up a second channel to send responses back to the local queue manager.

Use the MQSC command DEFINE CHANNEL to define channels. In this section, the examples relating to channels use the default channel attributes unless otherwise specified.

There is a message channel agent (MCA) at each end of a channel, controlling the sending and receiving of messages. The MCA takes messages from the transmission queue and puts them on the communication link between the queue managers.

A transmission queue is a specialized local queue that temporarily holds messages before the MCA picks them up and sends them to the remote queue manager. You specify the name of the transmission queue on a *remote queue definition*.

You can allow an MCA to transfer messages using multiple threads. This process is known as *pipelining*. Pipelining enables the MCA to transfer messages more efficiently, improving channel performance. See Attributes of channels for details of how to configure a channel to use pipelining.

"Preparing channels and transmission queues for remote administration" on page 133 tells you how to use these definitions to set up remote administration.

For more information about setting up distributed queuing in general, see Distributed queuing components.

Remote administration using clusters

In an IBM MQ network using distributed queuing, every queue manager is independent. If one queue manager needs to send messages to another queue manager, it must define a transmission queue, a channel to the remote queue manager, and a remote queue definition for every queue to which it wants to send messages.

A *cluster* is a group of queue managers set up in such a way that the queue managers can communicate directly with one another over a single network without complex transmission queue, channel, and queue definitions. Clusters can be set up easily, and typically contain queue managers that are logically related in some way and need to share data or applications. Even the smallest cluster reduces system administration costs.

Establishing a network of queue managers in a cluster involves fewer definitions than establishing a traditional distributed queuing environment. With fewer definitions to make, you can set up or change your network more quickly and easily, and reduce the risk of making an error in your definitions.

To set up a cluster, you need one cluster sender (CLUSSDR) and one cluster receiver (CLUSRCVR) definition for each queue manager. You do not need any transmission queue definitions or remote queue definitions. The principles of remote administration are the same when used within a cluster, but the definitions themselves are greatly simplified.

Remote administration from a local queue manager

This section tells you how to administer a remote queue manager from a local queue manager using MQSC and PCF commands.

Preparing the queues and channels is essentially the same for both MQSC and PCF commands. In this section, the examples show MQSC commands, because they are easier to understand. For more information about writing administration programs using PCF commands, see "Using Programmable Command Formats" on page 7.

You send MQSC commands to a remote queue manager either interactively or from a text file containing the commands. The remote queue manager might be on the same machine or, more typically, on a different machine. You can remotely administer queue managers in other IBM MQ environments, including UNIX and Linux systems, Windows systems, IBM i, and z/OS.

To implement remote administration, you must create specific objects. Unless you have specialized requirements, the default values (for example, for maximum message length) are sufficient.

Preparing queue managers for remote administration

How to use MQSC commands to prepare queue managers for remote administration.

Figure 16 shows the configuration of queue managers and channels that you need for remote administration using the **runmqsc** command. The object `source.queue.manager` is the source queue manager from which you can issue MQSC commands and to which the results of these commands (operator messages) are returned. The object `target.queue.manager` is the name of the target queue manager, which processes the commands and generates any operator messages.

Note: If you are using **runmqsc** with the -w option, `source.queue.manager` ***must*** be the default queue manager. For further information on creating a queue manager, see crtmqm.

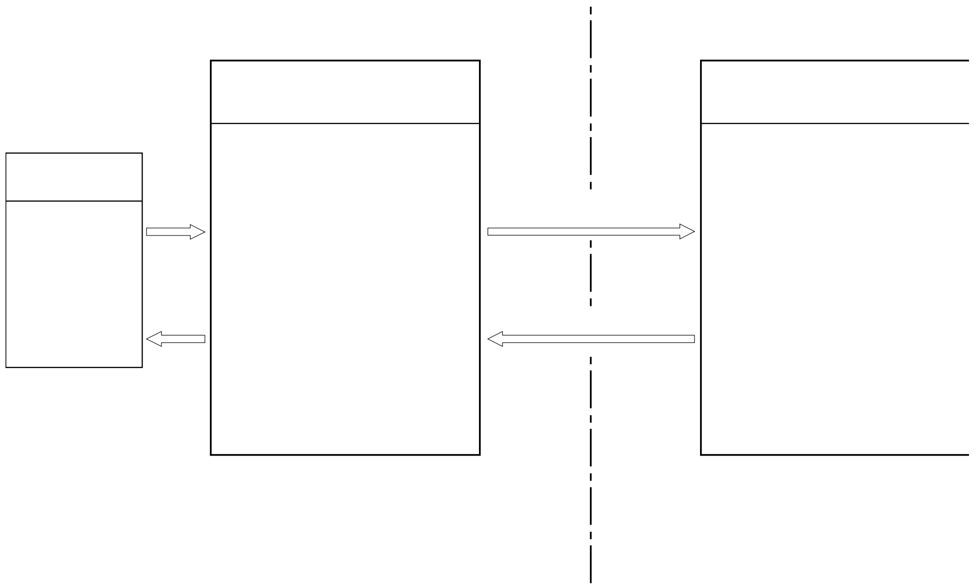

Figure 16. Remote administration using MQSC commands

On both systems, if you have not already done so:

- Create the queue manager and the default objects, using the **crtmqm** command.
- Start the queue manager, using the **strmqm** command.

On the target queue manager:

- The command queue, SYSTEM.ADMIN.COMMAND.QUEUE, must be present. This queue is created by default when a queue manager is created.

You have to run these commands locally or over a network facility such as Telnet.

Preparing channels and transmission queues for remote administration

How to use MQSC commands to prepare channels and transmission queues for remote administration.

To run MQSC commands remotely, set up two channels, one for each direction, and their associated transmission queues. This example assumes that you are using TCP/IP as the transport type and that you know the TCP/IP address involved.

The channel `source.to.target` is for sending MQSC commands from the source queue manager to the target queue manager. Its sender is at `source.queue.manager` and its receiver is at `target.queue.manager`. The channel `target.to.source` is for returning the output from commands and any operator messages that are generated to the source queue manager. You must also define a transmission queue for each channel. This queue is a local queue that is given the name of the receiving queue manager. The XMITQ name must match the remote queue manager name in order for remote administration to work, unless you are using a queue manager alias. Figure 17 summarizes this configuration.

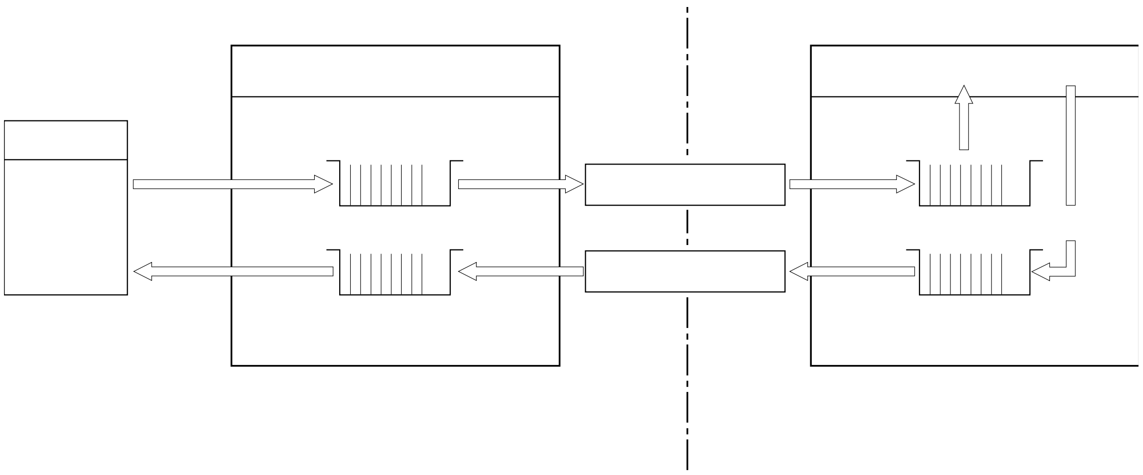

Figure 17. Setting up channels and queues for remote administration

See Configuring distributed queuing for more information about setting up channels.

Defining channels, listeners, and transmission queues:

On the source queue manager (`source.queue.manager`), issue the following MQSC commands to define the channels, listener, and the transmission queue:

1. Define the sender channel at the source queue manager:
```
DEFINE CHANNEL ('source.to.target') +
CHLTYPE(SDR) +
CONNAME (RHX5498) +
XMITQ ('target.queue.manager') +
TRPTYPE(TCP)
```
2. Define the receiver channel at the source queue manager:
```
DEFINE CHANNEL ('target.to.source') +
CHLTYPE(RCVR) +
TRPTYPE(TCP)
```
3. Define the listener on the source queue manager:
```
DEFINE LISTENER ('source.queue.manager') +
TRPTYPE (TCP)
```
4. Define the transmission queue on the source queue manager:
```
DEFINE QLOCAL ('target.queue.manager') +
USAGE (XMITQ)
```

Issue the following commands on the target queue manager (`target.queue.manager`), to create the channels, listener, and the transmission queue:

1. Define the sender channel on the target queue manager:
   ```
   DEFINE CHANNEL ('target.to.source') +
   CHLTYPE(SDR) +
   CONNAME (RHX7721) +
   XMITQ ('source.queue.manager') +
   TRPTYPE(TCP)
   ```
2. Define the receiver channel on the target queue manager:
   ```
   DEFINE CHANNEL ('source.to.target') +
   CHLTYPE(RCVR) +
   TRPTYPE(TCP)
   ```
3. Define the listener on the target queue manager:
   ```
   DEFINE LISTENER ('target.queue.manager') +
   TRPTYPE (TCP)
   ```
4. Define the transmission queue on the target queue manager:
   ```
   DEFINE QLOCAL ('source.queue.manager') +
   USAGE (XMITQ)
   ```

Note: The TCP/IP connection names specified for the CONNAME attribute in the sender channel definitions are for illustration only. This is the network name of the machine at the *other* end of the connection. Use the values appropriate for your network.

Starting the listeners and channels:

How to use MQSC commands to start listeners and channels.

Start both listeners by using the following MQSC commands:

1. Start the listener on the source queue manager, `source.queue.manager`, by issuing the following MQSC command:
   ```
   START LISTENER ('source.queue.manager')
   ```
2. Start the listener on the target queue manager, `target.queue.manager`, by issuing the following MQSC command:
   ```
   START LISTENER ('target.queue.manager')
   ```

Start both sender channels by using the following MQSC commands:

1. Start the sender channel on the source queue manager, `source.queue.manager`, by issuing the following MQSC command:
   ```
   START CHANNEL ('source.to.target')
   ```
2. Start the sender channel on the target queue manager, `target.queue.manager`, by issuing the following MQSC command:
   ```
   START CHANNEL ('target.to.source')
   ```

Automatic definition of channels:

You enable automatic definition of receiver and server-connection definitions by updating the queue manager object using the MQSC command, ALTER QMGR (or the PCF command Change Queue Manager).

If IBM MQ receives an inbound attach request and cannot find an appropriate receiver or server-connection channel, it creates a channel automatically. Automatic definitions are based on two default definitions supplied with IBM MQ: SYSTEM.AUTO.RECEIVER and SYSTEM.AUTO.SVRCONN.

For more information about creating channel definitions automatically, see Preparing channels. For information about automatically defining channels for clusters, see Working with auto-defined channels.

Managing the command server for remote administration

How to start, stop, and display the status of the command server. A command server is mandatory for all administration involving PCF commands, the MQAI, and also for remote administration.

Each queue manager can have a command server associated with it. A command server processes any incoming commands from remote queue managers, or PCF commands from applications. It presents the commands to the queue manager for processing and returns a completion code or operator message depending on the origin of the command.

Note: For remote administration, ensure that the target queue manager is running. Otherwise, the messages containing commands cannot leave the queue manager from which they are issued. Instead, these messages are queued in the local transmission queue that serves the remote queue manager. Avoid this situation.

There are separate control commands for starting and stopping the command server. Providing the command server is running, users of IBM MQ for Windows or IBM MQ for Linux (x86 and x86-64 platforms) can perform the operations described in the following sections using the IBM MQ Explorer. For more information, see “Administration using the MQ Explorer” on page 56.

Starting the command server

Depending on the value of the queue manager attribute, *SCMDSERV*, the command server is either started automatically when the queue manager starts, or must be started manually. The value of the queue manager attribute can be altered using the MQSC command `ALTER QMGR` specifying the parameter `SCMDSERV`. By default, the command server is started automatically.

If *SCMDSERV* is set to MANUAL, start the command server using the command:

```
strmqcsv saturn.queue.manager
```

where `saturn.queue.manager` is the queue manager for which the command server is being started.

Displaying the status of the command server

For remote administration, ensure that the command server on the target queue manager is running. If it is not running, remote commands cannot be processed. Any messages containing commands are queued in the target queue manager's command queue.

To display the status of the command server for a queue manager, issue the following MQSC command:

```
DISPLAY QMSTATUS CMDSERV
```

Stopping a command server

To end the command server started by the previous example use the following command:

```
endmqcsv saturn.queue.manager
```

You can stop the command server in two ways:
- For a controlled stop, use the **endmqcsv** command with the -c flag, which is the default.
- For an immediate stop, use the **endmqcsv** command with the -i flag.

Note: Stopping a queue manager also ends the command server associated with it.

Issuing MQSC commands on a remote queue manager

You can use a particular form of the `runmqsc` command to run MQSC commands on a remote queue manager.

The command server ***must*** be running on the target queue manager, if it is going to process MQSC commands remotely. (This is not necessary on the source queue manager). For information on how to start the command server on a queue manager, see "Managing the command server for remote administration" on page 135.

On the source queue manager, you can then run MQSC commands interactively in indirect mode by typing:

```
runmqsc -w 30 target.queue.manager
```

This form of the **runmqsc** command, with the -w flag, runs the MQSC commands in indirect mode, where commands are put (in a modified form) on the command server input queue and executed in order.

When you type in an MQSC command, it is redirected to the remote queue manager, in this case, `target.queue.manager`. The timeout is set to 30 seconds; if a reply is not received within 30 seconds, the following message is generated on the local (source) queue manager:

```
AMQ8416: MQSC timed out waiting for a response from the command server.
```

When you stop issuing MQSC commands, the local queue manager displays any timed-out responses that have arrived and discards any further responses.

The source queue manager defaults to the default local queue manager. If you specify the `-m` *LocalQmgrName* option in the `runmqsc` command, you can direct the commands to be issued by way of any local queue manager.

In indirect mode, you can also run an MQSC command file on a remote queue manager. For example:

```
runmqsc -w 60 target.queue.manager < mycomds.in > report.out
```

where `mycomds.in` is a file containing MQSC commands and `report.out` is the report file.

Suggested method for issuing commands remotely

When you are issuing commands on a remote queue manager, consider using the following approach:
1. Put the MQSC commands to be run on the remote system in a command file.
2. Verify your MQSC commands locally, by specifying the -v flag on the **runmqsc** command.
   You cannot use **runmqsc** to verify MQSC commands on another queue manager.
3. Check that the command file runs locally without error.
4. Run the command file on the remote system.

If you have problems using MQSC commands remotely

If you have difficulty in running MQSC commands remotely, make sure that you have:
- Started the command server on the target queue manager.
- Defined a valid transmission queue.
- Defined the two ends of the message channels for both:
  - The channel along which the commands are being sent.
  - The channel along which the replies are to be returned.
- Specified the correct connection name (CONNAME) in the channel definition.
- Started the listeners before you started the message channels.
- Checked that the disconnect interval has not expired, for example, if a channel started but then shut down after some time. This is especially important if you start the channels manually.
- Sent requests from a source queue manager that do not make sense to the target queue manager (for example, requests that include parameters that are not supported on the remote queue manager).

See also "Resolving problems with MQSC commands" on page 81.

Working with queue managers on z/OS:

You can issue MQSC commands to a z/OS queue manager from a queue manager on the platforms described in this guide. However, to do this, you must modify the **runmqsc** command and the channel definitions at the sender.

In particular, you add the -x flag to the **runmqsc** command on the source node to specify that the target queue manager is running under z/OS:

```
runmqsc -w 30 -x target.queue.manager
```

Creating a local definition of a remote queue

A local definition of a remote queue is a definition on a local queue manager that refers to a queue on a remote queue manager.

You do not have to define a remote queue from a local position, but the advantage of doing so is that applications can refer to the remote queue by its locally-defined name instead of having to specify a name that is qualified by the ID of the queue manager on which the remote queue is located.

Understanding how local definitions of remote queues work

An application connects to a local queue manager and then issues an **MQOPEN** call. In the open call, the queue name specified is that of a remote queue definition on the local queue manager. The remote queue definition supplies the names of the target queue, the target queue manager, and optionally, a transmission queue. To put a message on the remote queue, the application issues an **MQPUT** call, specifying the handle returned from the **MQOPEN** call. The queue manager uses the remote queue name and the remote queue manager name in a transmission header at the start of the message. This information is used to route the message to its correct destination in the network.

As administrator, you can control the destination of the message by altering the remote queue definition.

The following example shows how an application puts a message on a queue owned by a remote queue manager. The application connects to a queue manager, for example, `saturn.queue.manager`. The target queue is owned by another queue manager.

On the **MQOPEN** call, the application specifies these fields:

Field value	Description
ObjectName CYAN.REMOTE.QUEUE	Specifies the local name of the remote queue object. This defines the target queue and the target queue manager.
ObjectType (Queue)	Identifies this object as a queue.
ObjectQmgrName Blank or `saturn.queue.manager`	This field is optional. If blank, the name of the local queue manager is assumed. (This is the queue manager on which the remote queue definition exists.)

After this, the application issues an **MQPUT** call to put a message onto this queue.

On the local queue manager, you can create a local definition of a remote queue using the following MQSC commands:

```
DEFINE QREMOTE (CYAN.REMOTE.QUEUE) +
DESCR ('Queue for auto insurance requests from the branches') +
RNAME (AUTOMOBILE.INSURANCE.QUOTE.QUEUE) +
RQMNAME (jupiter.queue.manager) +
XMITQ (INQUOTE.XMIT.QUEUE)
```

where:

`QREMOTE (CYAN.REMOTE.QUEUE)`
Specifies the local name of the remote queue object. This is the name that applications connected to this queue manager must specify in the **MQOPEN** call to open the queue AUTOMOBILE.INSURANCE.QUOTE.QUEUE on the remote queue manager `jupiter.queue.manager`.

`DESCR ('Queue for auto insurance requests from the branches')`
Provides additional text that describes the use of the queue.

`RNAME (AUTOMOBILE.INSURANCE.QUOTE.QUEUE)`
Specifies the name of the target queue on the remote queue manager. This is the real target queue for messages sent by applications that specify the queue name CYAN.REMOTE.QUEUE. The queue AUTOMOBILE.INSURANCE.QUOTE.QUEUE must be defined as a local queue on the remote queue manager.

`RQMNAME (jupiter.queue.manager)`
Specifies the name of the remote queue manager that owns the target queue AUTOMOBILE.INSURANCE.QUOTE.QUEUE.

`XMITQ (INQUOTE.XMIT.QUEUE)`
Specifies the name of the transmission queue. This is optional; if the name of a transmission queue is not specified, a queue with the same name as the remote queue manager is used.

In either case, the appropriate transmission queue must be defined as a local queue with a *Usage* attribute specifying that it is a transmission queue (USAGE(XMITQ) in MQSC commands).

An alternative way of putting messages on a remote queue

Using a local definition of a remote queue is not the only way of putting messages on a remote queue. Applications can specify the full queue name, including the remote queue manager name, as part of the **MQOPEN** call. In this case, you do not need a local definition of a remote queue. However, this means that applications must either know, or have access to, the name of the remote queue manager at run time.

Using other commands with remote queues

You can use MQSC commands to display or alter the attributes of a remote queue object, or you can delete the remote queue object. For example:

- To display the remote queue's attributes:
  ```
  DISPLAY QUEUE (CYAN.REMOTE.QUEUE)
  ```
- To change the remote queue to enable puts. This does not affect the target queue, only applications that specify this remote queue:
  ```
  ALTER QREMOTE (CYAN.REMOTE.QUEUE) PUT(ENABLED)
  ```
- To delete this remote queue. This does not affect the target queue, only its local definition:
  ```
  DELETE QREMOTE (CYAN.REMOTE.QUEUE)
  ```

Note: When you delete a remote queue, you delete only the local representation of the remote queue. You do not delete the remote queue itself or any messages on it.

Defining a transmission queue

A transmission queue is a local queue that is used when a queue manager forwards messages to a remote queue manager through a message channel.

The channel provides a one-way link to the remote queue manager. Messages are queued at the transmission queue until the channel can accept them. When you define a channel, you must specify a transmission queue name at the sending end of the message channel.

The MQSC command attribute USAGE defines whether a queue is a transmission queue or a normal queue.

Default transmission queues

When a queue manager sends messages to a remote queue manager, it identifies the transmission queue using the following sequence:

1. The transmission queue named on the XMITQ attribute of the local definition of a remote queue.
2. A transmission queue with the same name as the target queue manager. (This value is the default value on XMITQ of the local definition of a remote queue.)
3. The transmission queue named on the DEFXMITQ attribute of the local queue manager.

For example, the following MQSC command creates a default transmission queue on `source.queue.manager` for messages going to `target.queue.manager`:

```
DEFINE QLOCAL ('target.queue.manager') +
DESCR ('Default transmission queue for target qm') +
USAGE (XMITQ)
```

Applications can put messages directly on a transmission queue, or indirectly through a remote queue definition. See also “Creating a local definition of a remote queue” on page 137.

Checking that async commands for distributed networks have finished

Many commands are asynchronous when used in a distributed network. Depending on the command, and the network state when it is issued, it can take a significant amount of time to finish. The queue manager does not issue a message on completion, so you need other ways of checking that the command has finished.

About this task

Almost any configuration change that you make to a cluster is likely to complete asynchronously. This is because of the internal administration and updating cycles that operate within clusters. For publish/subscribe hierarchies, any configuration change that affects subscriptions is likely to complete asynchronously. This is not always obvious from the name of the command.

The following MQSC commands might all complete asynchronously. Each of these commands has a PCF equivalent, and most are also available from within MQ Explorer . When run on a small network with no workload, these commands typically complete within a few seconds. However, this is not the case for larger and busier networks. Also, the **`REFRESH CLUSTER`** command might take much longer, particularly when it is issued on multiple queue managers at the same time.

To have confidence that these commands have finished, check that the expected objects exist on the remote queue managers.

Procedure

- ALTER QMGR

  For the ALTER QMGR PARENT command, use `DISPLAY PUBSUB TYPE(PARENT) ALL` to track the status of the requested parent relationship.

  For the ALTER QMGR REPOS and ALTER QMGR REPOSNL commands, use `DISPLAY CLUSQMGR QMTYPE` to confirm completion.
- DEFINE CHANNEL, ALTER CHANNEL, and DELETE CHANNEL

  For all parameters listed in the table ALTER CHANNEL parameters, use the `DISPLAY CLUSQMGR` command to monitor when changes have been propagated to the cluster.
- DEFINE NAMELIST, ALTER NAMELIST, and DELETE NAMELIST.

  If you use a **`NAMELIST`** on the **`CLUSNL`** attribute of a **`QMgr`** object, a queue or a cluster channel might affect that object. Monitor as appropriate for the affected object.

  Changes to `SYSTEM.QPUBSUB.QUEUE.NAMELIST` might affect creation or cancellation of proxy subscriptions in a publish/subscribe hierarchy. Use the `DISPLAY SUB SUBTYPE(PROXY)` command to monitor this.
- DEFINE queues, ALTER queues, and DELETE queues.

  For all parameters listed in the table Parameters that can be returned by the DISPLAY QUEUE command, use the `DISPLAY QCLUSTER` command to monitor when changes have been propagated to the cluster.
- DEFINE SUB, and DELETE SUB

  When you define the first subscription on a topic string, you might create proxy subscriptions in a publish/subscribe hierarchy or publish/subscribe cluster. Similarly, when you delete the last subscription on a topic string, you might cancel proxy subscriptions in a publish/subscribe hierarchy or publish/subscribe cluster.

  To check that a command defining or deleting a subscription has finished, check whether or not the expected proxy subscription exists on other queue managers in the distributed network. If you are using *direct routing* in a cluster, check that the expected proxy subscription exists on the other partial repositories in the cluster. If you are using *topic host routing* in a cluster, check that the expected proxy subscription exists on the matching topic hosts. Use the following MQSC command:

  ```
  DISPLAY SUB(*) SUBTYPE(PROXY)
  ```

Use the same check for the following equivalent subscribe and unsubscribe MQI calls, when they are issued in a cluster or hierarchy:

– Subscribe by using MQSUB.
– Unsubscribe by using MQCLOSE with MQCO_REMOVE_SUB.

- DEFINE TOPIC, ALTER TOPIC, and DELETE TOPIC

  To check that a command defining, altering or deleting a clustered topic has finished, display the topic in the other partial repositories in the cluster (if you are using *direct routing*) or on the other topic hosts (if you are using *topic host routing*).

  For all parameters listed in the table Parameters that can be returned by the DISPLAY TOPIC command, use the `DISPLAY TCLUSTER` command to monitor when changes have been propagated to the cluster.

  Note:

  – The **CLUSTER** parameter can affect creation or cancellation of proxy subscriptions in a publish/subscribe cluster.
  – The **PROXYSUB** and **SUBSCOPE** parameters can affect creation or cancellation of proxy subscriptions in a publish/subscribe hierarchy or publish/subscribe cluster.
  – Use the `DISPLAY SUB SUBTYPE(PROXYSUB)` command to monitor this.

- REFRESH CLUSTER

  If you are running the **REFRESH CLUSTER** command, poll the cluster command queue depth. Wait for it to reach zero, and remain at zero, before looking for the objects.

  1. Use the following MQSC command to check that the cluster command queue depth is zero.
     ```
     DISPLAY QL(SYSTEM.CLUSTER.COMMAND.QUEUE) CURDEPTH
     ```
  2. Repeat the check until the queue depth reaches zero, and remains at zero in the subsequent check.

  The **REFRESH CLUSTER** command removes and recreates objects, and in large configurations can take a significant time to complete. See REFRESH CLUSTER considerations for publish/subscribe clusters.

- REFRESH QMGR TYPE(PROXYSUB)

  To check that the **REFRESH QMGR TYPE(PROXYSUB)** command has finished, check that the proxy subscriptions have been corrected on other queue managers in the distributed network. If you are using *direct routing* in a cluster, check that the proxy subscriptions have been corrected on the other partial repositories in the cluster. If you are using *topic host routing* in a cluster, check that the expected proxy subscriptions have been corrected on the matching topic hosts. Use the following MQSC command:

  ```
  DISPLAY SUB(*) SUBTYPE(PROXYSUB)
  ```

- RESET CLUSTER

  To check that the **RESET CLUSTER** command has completed, use `DISPLAY CLUSQMGR`.

- RESET QMGR TYPE(PUBSUB)

  To check that the **RESET QMGR** command has completed, use `DISPLAY PUBSUB TYPE(PARENT|CHILD)`.

  Note: The **RESET QMGR** command might cause cancellation of proxy subscriptions in a publish/subscribe hierarchy or publish/subscribe cluster. Use the `DISPLAY SUB SUBTYPE(PROXYSUB)` command to monitor this.

- You might also want to monitor other system queues that, as and when commands complete, tend towards a queue depth of zero. For example, you might want to monitor the `SYSTEM.INTER.QMGR.CONTROL` queue, and the `SYSTEM.INTER.QMGR.FANREQ` queue. See Monitoring proxy subscription traffic in clusters and Balancing producers and consumers in publish/subscribe networks.

What to do next

If these checks do not confirm that an asynchronous command has finished, an error might have occurred. To investigate, first check the log for the queue manager on which the command was issued, then (for a cluster) check the cluster full repository logs.

Using remote queue definitions as aliases

In addition to locating a queue on another queue manager, you can also use a local definition of a remote queue for Queue manager aliases and reply-to queue aliases. Both types of alias are resolved through the local definition of a remote queue. You must set up the appropriate channels for the message to arrive at its destination.

Queue manager aliases

An alias is the process by which the name of the target queue manager, as specified in a message, is modified by a queue manager on the message route. Queue manager aliases are important because you can use them to control the destination of messages within a network of queue managers.

You do this by altering the remote queue definition on the queue manager at the point of control. The sending application is not aware that the queue manager name specified is an alias.

For more information about queue manager aliases, see What are aliases?.

Reply-to queue aliases

Optionally, an application can specify the name of a reply-to queue when it puts a *request message* on a queue.

If the application that processes the message extracts the name of the reply-to queue, it knows where to send the *reply message*, if required.

A reply-to queue alias is the process by which a reply-to queue, as specified in a request message, is altered by a queue manager on the message route. The sending application is not aware that the reply-to queue name specified is an alias.

A reply-to queue alias lets you alter the name of the reply-to queue and optionally its queue manager. This in turn lets you control which route is used for reply messages.

For more information about request messages, reply messages, and reply-to queues, see Types of message and Reply-to queue and queue manager.

For more information about reply-to queue aliases, see Reply-to queue aliases and clusters.

Data conversion

Message data in IBM MQ defined formats (also known as *built-in formats*) can be converted by the queue manager from one coded character set to another, provided that both character sets relate to a single language or a group of similar languages.

For example, conversion between coded character sets with identifiers (CCSIDs) 850 and 500 is supported, because both apply to Western European languages.

For EBCDIC newline (NL) character conversions to ASCII, see All queue managers.

Supported conversions are defined in Data conversion.

When a queue manager cannot convert messages in built-in formats

The queue manager cannot automatically convert messages in built-in formats if their CCSIDs represent different national-language groups. For example, conversion between CCSID 850 and CCSID 1025 (which is an EBCDIC coded character set for languages using Cyrillic script) is not supported because many of the characters in one coded character set cannot be represented in the other. If you have a network of queue managers working in different national languages, and data conversion among some of the coded character sets is not supported, you can enable a default conversion. Default data conversion is described in "Default data conversion."

File ccsid.tbl

The file ccsid.tbl is used for the following purposes:

- In IBM MQ for Windows it records all the supported code sets.
- On AIX and HP-UX platforms, the supported code sets are held internally by the operating system.
- For all other UNIX and Linux platforms, the supported code sets are held in conversion tables provided by IBM MQ.
- It specifies any additional code sets. To specify additional code sets, you need to edit ccsid.tbl (guidance on how to do this is provided in the file).
- It specifies any default data conversion.

You can update the information recorded in ccsid.tbl; you might want to do this if, for example, a future release of your operating system supports additional coded character sets.

In IBM MQ for Windows, ccsid.tbl is located in directory `C:\Program Files\IBM\WebSphere MQ\conv\table` by default.

In IBM MQ for UNIX and Linux systems, ccsid.tbl is located in directory `/var/mqm/conv/table`.

Default data conversion

If you set up channels between two machines on which data conversion is not normally supported, you must enable default data conversion for the channels to work.

To enable default data conversion, edit the ccsid.tbl file to specify a default EBCDIC CCSID and a default ASCII CCSID. Instructions on how to do this are included in the file. You must do this on all machines that will be connected using the channels. Restart the queue manager for the change to take effect.

The default data-conversion process is as follows:

- If conversion between the source and target CCSIDs is not supported, but the CCSIDs of the source and target environments are either both EBCDIC or both ASCII, the character data is passed to the target application without conversion.

- If one CCSID represents an ASCII coded character set, and the other represents an EBCDIC coded character set, IBM MQ converts the data using the default data-conversion CCSIDs defined in ccsid.tbl.

Note: Try to restrict the characters being converted to those that have the same code values in the coded character set specified for the message and in the default coded character set. If you use only the set of characters that is valid for IBM MQ object names (as defined in Naming IBM MQ objects) you will, in general, satisfy this requirement. Exceptions occur with EBCDIC CCSIDs 290, 930, 1279, and 5026 used in Japan, where the lowercase characters have different codes from those used in other EBCDIC CCSIDs.

Converting messages in user-defined formats

The queue manager cannot convert messages in user-defined formats from one coded character set to another. If you need to convert data in a user-defined format, you must supply a data-conversion exit for each such format. Do not use default CCSIDs to convert character data in user-defined formats. For more information about converting data in user-defined formats and about writing data conversion exits, see the Writing data-conversion exits.

Changing the queue manager CCSID

When you have used the CCSID attribute of the ALTER QMGR command to change the CCSID of the queue manager, stop and restart the queue manager to ensure that all running applications, including the command server and channel programs, are stopped and restarted.

This is necessary because any applications that are running when the queue manager CCSID is changed continue to use the existing CCSID.

Administering IBM MQ Telemetry

IBM MQ Telemetry is administered using MQ Explorer or at a command line. Use the explorer to configure telemetry channels, control the telemetry service, and monitor the MQTT clients that are connected to IBM MQ. Configure the security of IBM MQ Telemetry using JAAS, SSL and the IBM MQ object authority manager.

Administering using MQ Explorer

Use the explorer to configure telemetry channels, control the telemetry service, and monitor the MQTT clients that are connected to IBM MQ. Configure the security of IBM MQ Telemetry using JAAS, SSL and the IBM MQ object authority manager.

Administering using the command line

IBM MQ Telemetry can be completely administered at the command line using the IBM MQ MQSC commands.

The IBM MQ Telemetry documentation also has sample scripts that demonstrate the basic usage of the IBM MQ Telemetry Transport v3 Client application.

Read and understand the samples in IBM MQ Telemetry Transport sample programs in the Developing applications for IBM MQ Telemetry section before using them.

MQXR properties

Configuring a queue manager for telemetry on Linux and AIX

Follow these manual steps to configure a queue manager to run IBM MQ Telemetry. You can run an automated procedure to set up a simpler configuration using the IBM MQ Telemetry support for MQ Explorer.

Before you begin

1. See Installing IBM MQ Telemetry for information on how to install IBM MQ, and the IBM MQ Telemetry feature.
2. Create and start a queue manager. The queue manager is referred to as *qMgr* in this task.
3. As part of this task you configure the telemetry (MQXR) service. The MQXR property settings are stored in a platform-specific properties file: `mqxr_win.properties` or `mqxr_unix.properties`. You do not normally need to edit the MQXR properties file directly, because almost all settings can be configured through MQSC admin commands or MQ Explorer. If you do decide to edit the file directly, stop the queue manager before you make your changes. See MQXR properties.

About this task

The IBM MQ Telemetry support for MQ Explorer includes a wizard, and a sample command procedure `sampleMQM`. They set up an initial configuration using the guest user ID; see Verifying the installation of IBM MQ Telemetry by using MQ Explorer and IBM MQ Telemetry Transport sample programs.

Follow the steps in this task to configure IBM MQ Telemetry manually using different authorization schemes.

Procedure

1. Open a command window at the telemetry samples directory.

   The telemetry samples directory is `/opt/mqm/mqxr/samples`.
2. Create the telemetry transmission queue.
   ```
   echo "DEFINE QLOCAL('SYSTEM.MQTT.TRANSMIT.QUEUE') USAGE(XMITQ) MAXDEPTH(100000)" | runmqsc qMgr
   ```
   When the telemetry (MQXR) service is first started, it creates `SYSTEM.MQTT.TRANSMIT.QUEUE`.

   It is created manually in this task, because `SYSTEM.MQTT.TRANSMIT.QUEUE` must exist before the telemetry (MQXR) service is started, to authorize access to it.
3. Set the default transmission queue for *qMgr*
   ```
   echo "ALTER QMGR DEFXMITQ('SYSTEM.MQTT.TRANSMIT.QUEUE')" | runmqsc qMgr
   ```
   When the telemetry (MQXR) service is first started, it does not alter the queue manager to make `SYSTEM.MQTT.TRANSMIT.QUEUE` the default transmission queue.

   To make `SYSTEM.MQTT.TRANSMIT.QUEUE` the default transmission queue alter the default transmission queue property. Alter the property using the MQ Explorer or with the command in Figure 19 on page 147.

   Altering the default transmission queue might interfere with your existing configuration. The reason for altering the default transmission queue to `SYSTEM.MQTT.TRANSMIT.QUEUE` is to make sending messages directly to MQTT clients easier. Without altering the default transmission queue you must add a remote queue definition for every client that receives IBM MQ messages; see “Sending a message to a client directly” on page 149.
4. Follow a procedure in “Authorizing MQTT clients to access IBM MQ objects” on page 152 to create one or more user IDs. The user IDs have the authority to publish, subscribe, and send publications to MQTT clients.

5. Install the telemetry (MQXR) service

   `cat installMQXRService_unix.mqsc | runmqsc` *`qMgr`*
6. Start the service

   `echo "START SERVICE(SYSTEM.MQXR.SERVICE)" | runmqsc` *`qMgr`*

   The telemetry (MQXR) service is started automatically when the queue manager is started.

   It is started manually in this task, because the queue manager is already running.
7. Using MQ Explorer, configure telemetry channels to accept connections from MQTT clients.
8. Verify the configuration by running the sample client.

   For the sample client to work with your telemetry channel, the channel must authorize the client to publish, subscribe, and receive publications. The sample client connects to the telemetry channel on port 1883 by default.

Example

Figure 18 shows the **`runmqsc`** command to create the `SYSTEM.MQXR.SERVICE` manually on Linux.

```
DEF SERVICE(SYSTEM.MQXR.SERVICE) +
CONTROL(QMGR) +
DESCR('Manages clients using MQXR protocols such as MQTT') +
SERVTYPE(SERVER) +
STARTCMD('+MQ_INSTALL_PATH+/mqxr/bin/runMQXRService.sh') +
STARTARG('-m +QMNAME+ -d "+MQ_Q_MGR_DATA_PATH+" -g "+MQ_DATA_PATH+"') +
STOPCMD('+MQ_INSTALL_PATH+/mqxr/bin/endMQXRService.sh') +
STOPARG('-m +QMNAME+') +
STDOUT('+MQ_Q_MGR_DATA_PATH+/mqxr.stdout') +
STDERR('+MQ_Q_MGR_DATA_PATH+/mqxr.stderr')
```

Figure 18. `installMQXRService_unix.mqsc`

Configuring a queue manager for telemetry on Windows

Follow these manual steps to configure a queue manager to run IBM MQ Telemetry. You can run an automated procedure to set up a simpler configuration using the IBM MQ Telemetry support for MQ Explorer.

Before you begin

1. See Installing IBM MQ Telemetry for information on how to install IBM MQ, and the IBM MQ Telemetry feature.
2. Create and start a queue manager. The queue manager is referred to as *`qMgr`* in this task.
3. As part of this task you configure the telemetry (MQXR) service. The MQXR property settings are stored in a platform-specific properties file: `mqxr_win.properties` or `mqxr_unix.properties`. You do not normally need to edit the MQXR properties file directly, because almost all settings can be configured through MQSC admin commands or MQ Explorer. If you do decide to edit the file directly, stop the queue manager before you make your changes. See MQXR properties.

About this task

The IBM MQ Telemetry support for MQ Explorer includes a wizard, and a sample command procedure `sampleMQM`. They set up an initial configuration using the guest user ID; see Verifying the installation of IBM MQ Telemetry by using MQ Explorer and IBM MQ Telemetry Transport sample programs.

Follow the steps in this task to configure IBM MQ Telemetry manually using different authorization schemes.

Procedure

1. Open a command window at the telemetry samples directory.

   The telemetry samples directory is `WMQ program installation directory\mqxr\samples`.
2. Create the telemetry transmission queue.

   ```
   echo DEFINE QLOCAL('SYSTEM.MQTT.TRANSMIT.QUEUE') USAGE(XMITQ) MAXDEPTH(100000) | runmqsc qMgr
   ```

   When the telemetry (MQXR) service is first started, it creates `SYSTEM.MQTT.TRANSMIT.QUEUE`.

   It is created manually in this task, because `SYSTEM.MQTT.TRANSMIT.QUEUE` must exist before the telemetry (MQXR) service is started, to authorize access to it.
3. Set the default transmission queue for *qMgr*

```
echo ALTER QMGR DEFXMITQ('SYSTEM.MQTT.TRANSMIT.QUEUE') | runmqsc qMgr
```

Figure 19. Set default transmission queue

   When the telemetry (MQXR) service is first started, it does not alter the queue manager to make `SYSTEM.MQTT.TRANSMIT.QUEUE` the default transmission queue.

   To make `SYSTEM.MQTT.TRANSMIT.QUEUE` the default transmission queue alter the default transmission queue property. Alter the property using the MQ Explorer or with the command in Figure 19.

   Altering the default transmission queue might interfere with your existing configuration. The reason for altering the default transmission queue to `SYSTEM.MQTT.TRANSMIT.QUEUE` is to make sending messages directly to MQTT clients easier. Without altering the default transmission queue you must add a remote queue definition for every client that receives IBM MQ messages; see "Sending a message to a client directly" on page 149.
4. Follow a procedure in "Authorizing MQTT clients to access IBM MQ objects" on page 152 to create one or more user IDs. The user IDs have the authority to publish, subscribe, and send publications to MQTT clients.
5. Install the telemetry (MQXR) service

   ```
   type installMQXRService_win.mqsc | runmqsc qMgr
   ```
6. Start the service

   ```
   echo START SERVICE(SYSTEM.MQXR.SERVICE) | runmqsc qMgr
   ```

   The telemetry (MQXR) service is started automatically when the queue manager is started.

   It is started manually in this task, because the queue manager is already running.
7. Using MQ Explorer, configure telemetry channels to accept connections from MQTT clients.

   The telemetry channels must be configured such that their identities are one of the user IDs defined in step 4.
8. Verify the configuration by running the sample client.

   For the sample client to work with your telemetry channel, the channel must authorize the client to publish, subscribe, and receive publications. The sample client connects to the telemetry channel on port 1883 by default.

Creating `SYSTEM.MQXR.SERVICE` manually

Figure 20 on page 148 shows the **`runmqsc`** command to create the `SYSTEM.MQXR.SERVICE` manually on Windows.

```
DEF SERVICE(SYSTEM.MQXR.SERVICE) +
CONTROL(QMGR) +
DESCR('Manages clients using MQXR protocols such as MQTT') +
SERVTYPE(SERVER) +
STARTCMD('+MQ_INSTALL_PATH+\mqxr\bin\runMQXRService.bat') +
STARTARG('-m +QMNAME+ -d "+MQ_Q_MGR_DATA_PATH+\." -g "+MQ_DATA_PATH+\."') +
STOPCMD('+MQ_INSTALL_PATH+\mqxr\bin\endMQXRService.bat') +
STOPARG('-m +QMNAME+') +
STDOUT('+MQ_Q_MGR_DATA_PATH+\mqxr.stdout') +
STDERR('+MQ_Q_MGR_DATA_PATH+\mqxr.stderr')
```

Figure 20. `installMQXRService_win.mqsc`

Configure distributed queuing to send messages to MQTT clients

IBM MQ applications can send MQTT v3 clients messages by publishing to subscription created by a client, or by sending a message directly. Whichever method is used, the message is placed on `SYSTEM.MQTT.TRANSMIT.QUEUE`, and sent to the client by the telemetry (MQXR) service. There are a number of ways to place a message on `SYSTEM.MQTT.TRANSMIT.QUEUE`.

Publishing a message in response to an MQTT client subscription

The telemetry (MQXR) service creates a subscription on behalf of the MQTT client. The client is the destination for any publications that match the subscription sent by the client. The telemetry services forwards matching publications back to the client.

An MQTT client is connected to IBM MQ as a queue manager, with its queue manager name set to its `ClientIdentifier`. The destination for publications to be sent to the client is a transmission queue, `SYSTEM.MQTT.TRANSMIT.QUEUE`. The telemetry service forwards messages on `SYSTEM.MQTT.TRANSMIT.QUEUE` to MQTT clients, using the target queue manager name as the key to a specific client.

The telemetry (MQXR) service opens the transmission queue using `ClientIdentifier` as the queue manager name. The telemetry (MQXR) service passes the object handle of the queue to the MQSUB call, to forward publications that match the client subscription. In the object name resolution, the ClientIdentifier is created as the remote queue manager name, and the transmission queue must resolve to `SYSTEM.MQTT.TRANSMIT.QUEUE`. Using standard IBM MQ object name resolution, *`ClientIdentifier`* is resolved as follows; see Table 2 on page 149.

1. *`ClientIdentifier`* matches nothing.

   `ClientIdentifier` is a remote queue manager name. It does not match the local queue manager name, a queue manager alias, or a transmission queue name.

   The queue name is not defined. Currently, the telemetry (MQXR) service sets `SYSTEM.MQTT.PUBLICATION.QUEUE` as the name of the queue. An MQTT v3 client does not support queues, so the resolved queue name is ignored by the client.

   The local queue manager property, `Default transmission queue`, name must be set to `SYSTEM.MQTT.TRANSMIT.QUEUE`, so that the publication is put on `SYSTEM.MQTT.TRANSMIT.QUEUE` to be sent to the client.
2. *`ClientIdentifier`* matches a queue manager alias named *`ClientIdentifier`*.

   `ClientIdentifier` is a remote queue manager name. It matches the name of a queue manager alias.

   The queue manager alias must be defined with *`ClientIdentifier`* as the remote queue manager name.

   By setting the transmission queue name in the queue manager alias definition it is not necessary for the default transmission to be set to `SYSTEM.MQTT.TRANSMIT.QUEUE`.

Table 2. Name resolution of an MQTT queue manager alias

	Input		Output		
`ClientIdentifier`	**Queue manager name**	**Queue name**	**Queue manager name**	**Queue name**	**Transmission queue**
Matches nothing	*`ClientIdentifier`*	*undefined*	*`ClientIdentifier`*	*undefined*	Default transmission queue. `SYSTEM.MQTT.TRANSMIT.QUEUE`
Matches a queue manager alias named *`ClientIdentifier`*	*`ClientIdentifier`*	*undefined*	*`ClientIdentifier`*	*undefined*	`SYSTEM.MQTT.TRANSMIT.QUEUE`

For further information about name resolution, see Name resolution.

Any IBM MQ program can publish to the same topic. The publication is sent to its subscribers, including MQTT v3 clients that have a subscription to the topic.

If an administrative topic is created in a cluster, with the attribute `CLUSTER(clusterName)`, any application in the cluster can publish to the client; for example:

```
echo DEFINE TOPIC('MQTTExamples') TOPICSTR('MQTT Examples') CLUSTER(MQTT) REPLACE | runmqsc qMgr
```

Figure 21. Defining a cluster topic on Windows

Note: Do not give `SYSTEM.MQTT.TRANSMIT.QUEUE` a cluster attribute.

MQTT client subscribers and publishers can connect to different queue managers. The subscribers and publishers can be part of the same cluster, or connected by a publish/subscribe hierarchy. The publication is delivered from the publisher to the subscriber using IBM MQ.

Sending a message to a client directly

An alternative to a client creating a subscription and receiving a publication that matches the subscription topic, send a message to an MQTT v3 client directly. MQTT V3 client applications cannot send messages directly, but other application, such as IBM MQ applications, can.

The IBM MQ application must know the `ClientIdentifier` of the MQTT v3 client. As MQTT v3 clients to not have queues, the target queue name is passed to the MQTT v3 application client messageArrived method as a topic name. For example, in an MQI program, create an object descriptor with the client as the `ObjectQmgrName`:

```
MQOD.ObjectQmgrName = ClientIdentifier ;
MQOD.ObjectName = name ;
```

Figure 22. MQI Object descriptor to send a message to an MQTT v3 client destination

If the application is written using JMS, create a point-to-point destination; for example:

```
javax.jms.Destination jmsDestination =
(javax.jms.Destination)jmsFactory.createQueue
("queue://ClientIdentifier/name");
```

Figure 23. JMS destination to send a message to an MQTT v3 client

To send an unsolicited message to an MQTT client use a remote queue definition. The remote queue manager name must resolvedto the `ClientIdentifier` of the client. The transmission queue must resolve to `SYSTEM.MQTT.TRANSMIT.QUEUE` ; see Table 3. The remote queue name can be anything. The client receives it as a topic string.

Table 3. Name resolution of an MQTT client remote queue definition

Input		Output		
Queue name	**Queue manager name**	**Queue name**	**Queue manager name**	**Transmission queue**
Name of remote queue definition	Blank or local queue manager name	Remote queue name used as a topic string	*`ClientIdentifier`*	`SYSTEM.MQTT.TRANSMIT.QUEUE`

If the client is connected, the message is sent directly to the MQTT client, which calls the messageArrived method; see messageArrived method.

If the client has disconnected with a persistent session, the message is stored in `SYSTEM.MQTT.TRANSMIT.QUEUE` ; see MQTT stateless and stateful sessions. It is forwarded to the client when the client reconnects to the session again.

If you send a non-persistent message it is sent to the client with "at most once" quality of service, `QoS=0`. If you send a persistent message directly to a client, by default, it is sent with "exactly once" quality of service, `QoS=2`. As the client might not have a persistence mechanism, the client can lower the quality of service it accepts for messages sent directly. To lower the quality of service for messages sent directly to a client, make a subscription to the topic `DEFAULT.QoS`. Specify the maximum quality of service the client can support.

MQTT client identification, authorization, and authentication

The telemetry (MQXR) service publishes, or subscribes to, IBM MQ topics on behalf of MQTT clients, using MQTT channels. The IBM MQ administrator configures the MQTT channel identity that is used for IBM MQ authorization. The administrator can define a common identity for the channel, or use the `Username` or `ClientIdentifier` of a client connected to the channel.

The telemetry (MQXR) service can authenticate the client using the `Username` supplied by the client, or by using a client certificate. The `Username` is authenticated using a password provided by the client.

To summarize: Client identification is the selection of the client identity. Depending on the context, the client is identified by the `ClientIdentifier`, `Username`, a common client identity created by the administrator, or a client certificate. The client identifier used for authenticity checking does not have to be the same identifier that is used for authorization.

MQTT client programs set the `Username` and `Password` that are sent to the server using an MQTT channel. They can also set the SSL properties that are required to encrypt and authenticate the connection. The administrator decides whether to authenticate the MQTT channel, and how to authenticate the channel.

To authorize an MQTT client to access IBM MQ objects, authorize the `ClientIdentifier`, or `Username` of the client, or authorize a common client identity. To permit a client to connect to IBM MQ, authenticate the `Username`, or use a client certificate. Configure JAAS to authenticate the `Username`, and configure SSL to authenticate a client certificate.

If you set a `Password` at the client, either encrypt the connection using VPN, or configure the MQTT channel to use SSL, to keep the password private.

It is difficult to manage client certificates. For this reason, if the risks associated with password authentication are acceptable, password authentication is often used to authenticate clients.

If there is a secure way to manage and store the client certificate it is possible to rely on certificate authentication. However, it is rarely the case that certificates can be managed securely in the types of environments that telemetry is used in. Instead, the authentication of devices using client certificates is complemented by authenticating client passwords at the server. Because of the additional complexity, the use of client certificates is restricted to highly sensitive applications. The use of two forms of authentication is called two-factor authentication. You must know one of the factors, such as a password, and have the other, such as a certificate.

In a highly sensitive application, such as a chip-and-pin device, the device is locked down during manufacture to prevent tampering with the internal hardware and software. A trusted, time-limited, client certificate is copied to the device. The device is deployed to the location where it is to be used. Further authentication is performed each time the device is used, either using a password, or another certificate from a smart card.

MQTT client identity and authorization

Use the client ID, `Username`, or a common client identity for authorization to access IBM MQ objects.

The IBM MQ administrator has three choices for selecting the identity of the MQTT channel. The administrator makes the choice when defining or modifying the MQTT channel used by the client. The identity is used to authorize access to IBM MQ topics. The choice is made in the following order:

1. The client ID (see USECLNTID).
2. An identity the administrator provides for the channel (the `MCAUSER` of the channel. See MCAUSER).
3. If neither of the previous choices applies, the `Username` passed from the MQTT client (`Username` is an attribute of the MqttConnectOptions class. It must be set before the client connects to the service. Its default value is null).

Avoid trouble: The identity chosen by this process is thereafter referred to, for example by the DISPLAY CHSTATUS (MQTT) command, as the MCAUSER of the client. Be aware that this is not necessarily the same identity as the MCAUSER of the channel that is referred to in choice (2).

Use the IBM MQ **`setmqaut`** command to select which objects, and which actions, are authorized to be used by the identity associated with the MQTT channel. For example, the following code authorizes a channel identity `MQTTClient`, provided by the administrator of queue manager `QM1`:

```
 setmqaut -m QM1 -t q -n SYSTEM.MQTT.TRANSMIT.QUEUE -p MQTTClient -all +put
setmqaut -m QM1 -t topic -n SYSTEM.BASE.TOPIC -p MQTTClient -all +pub +sub
```

Authorizing MQTT clients to access IBM MQ objects:

Follow these steps to authorize MQTT clients to publish and subscribe to IBM MQ Objects. The steps follow four alternative access control patterns.

Before you begin

MQTT clients are authorized to access objects in IBM MQ by being assigned an identity when they connect to a telemetry channel. The IBM MQ Administrator configures the telemetry channel using IBM MQ Explorer to give a client one of three types of identity:

1. `ClientIdentifier`
2. `Username`
3. A name the administrator assigns to the channel.

Whichever type is used, the identity must be defined to IBM MQ as a principal by the installed authorization service. The default authorization service on Windows or Linux is called the Object Authority Manager (OAM). If you are using the OAM, the identity must be defined as a user ID.

Use the identity to give a client, or collection of clients, permission to publish or subscribe to topics defined in IBM MQ. If an MQTT client has subscribed to a topic, use the identity to give it permission to receive the resulting publications.

It is hard to manage a system with tens of thousands of MQTT clients, each requiring individual access permissions. One solution is to define common identities, and associate individual MQTT clients with one of the common identities. Define as many common identities as you require to define different combinations of permissions. Another solution is to write your own authorization service that can deal more easily with thousands of users than the operating system.

You can combine MQTT clients into common identities in two ways, using the OAM:

1. Define multiple telemetry channels, each with a different user ID that the administrator allocates using IBM MQ Explorer. Clients connecting using different TCP/IP port numbers are associated with different telemetry channels, and are assigned different identities.

2. Define a single telemetry channel, but have each client select a `Username` from a small set of user IDs. The administrator configures the telemetry channel to select the client `Username` as its identity.

In this task, the identity of the telemetry channel is called *mqttUser*, regardless of how it is set. If collections of clients use different identities, use multiple *mqttUsers*, one for each collection of clients. As the task uses the OAM, each *mqttUser* must be a user ID.

About this task

In this task, you have a choice of four access control patterns that you can tailor to specific requirements. The patterns differ in their granularity of access control.

- "No access control"
- "Coarse-grained access control"
- "Medium-grained access control"
- "Fine-grained access control" on page 154

The result of the models is to assign *mqttUsers* sets of permissions to publish and subscribe to IBM MQ, and receive publications from IBM MQ.

No access control:

MQTT clients are given IBM MQ administrative authority, and can perform any action on any object.

Procedure

1. Create a user ID *mqttUser* to act as the identity of all MQTT clients.
2. Add *mqttUser* to the `mqm` group; see Adding a user to a group on Windows , or Adding a user to a group on Linux

Coarse-grained access control:

MQTT clients have authority to publish and subscribe, and to send messages to MQTT clients. They do not have authority to perform other actions, or to access other objects.

Procedure

1. Create a user ID *mqttUser* to act as the identity of all MQTT clients.
2. Authorize *mqttUser* to publish and subscribe to all topics and to send publications to MQTT clients.
```
setmqaut -m qMgr -t topic -n SYSTEM.BASE.TOPIC -p mqttUser -all +pub +sub
setmqaut -m qMgr -t q -n SYSTEM.MQTT.TRANSMIT.QUEUE -p mqttUser -all +put
```

Medium-grained access control:

MQTT clients are divided into different groups to publish and subscribe to different sets of topics, and to send messages to MQTT clients.

Procedure

1. Create multiple user IDs, *mqttUsers*, and multiple administrative topics in the publish/subscribe topic tree.
2. Authorize different *mqttUsers* to different topics.
```
setmqaut -m qMgr -t topic -n topic1 -p mqttUserA -all +pub +sub
setmqaut -m qMgr -t topic -n topic2 -p mqttUserB -all +pub +sub
```
3. Create a group *mqtt*, and add all *mqttUsers* to the group.
4. Authorize *mqtt* to send topics to MQTT clients.
```
setmqaut -m qMgr -t q -n SYSTEM.MQTT.TRANSMIT.QUEUE -p mqtt -all +put
```

Fine-grained access control:

MQTT clients are incorporated into an existing system of access control, that authorizes groups to perform actions on objects.

About this task

A user ID is assigned to one or more operating system groups depending on the authorizations it requires. If IBM MQ applications are publishing and subscribing to the same topic space as MQTT clients, use this model. The groups are referred to as `Publish` *`X`*, `Subscribe` *`Y`*, and `mqtt`

`Publish` *`X`*
: Members of `Publish` *`X`* groups can publish to *`topicX`*.

`Subscribe` *`Y`*
: Members of `Subscribe` *`Y`* groups can subscribe to *`topicY`*.

`mqtt`
: Members of the *`mqtt`* group can send publications to MQTT clients.

Procedure

1. Create multiple groups, `Publish` *`X`* and `Subscribe` *`Y`* that are allocated to multiple administrative topics in the publish/subscribe topic tree.
2. Create a group `mqtt`.
3. Create multiple user IDs, *`mqttUsers`*, and add the users to any of the groups, depending on what they are authorized to do.
4. Authorize different `Publish` *`X`* and `Subscribe` *`X`* groups to different topics, and authorize the *`mqtt`* group to send messages to MQTT clients.

   ```
   setmqaut -m qMgr -t topic -n topic1 -p Publish X -all +pub
   setmqaut -m qMgr -t topic -n topic1 -p Subscribe X -all +pub +sub
   setmqaut -m qMgr -t q -n SYSTEM.MQTT.TRANSMIT.QUEUE -p mqtt -all +put
   ```

MQTT client authentication using a password

Authenticate the `Username` using the client password. You can authenticate the client using a different identity to the identity used to authorize the client to publish and subscribe to topics.

The telemetry (MQXR) service uses JAAS to authenticate the client `Username`. JAAS uses the `Password` supplied by the MQTT client.

The IBM MQ administrator decides whether to authenticate the `Username`, or not to authenticate at all, by configuring the MQTT channel a client connects to. Clients can be assigned to different channels, and each channel can be configured to authenticate its clients in different ways. Using JAAS, you can configure which methods must authenticate the client, and which can optionally authenticate the client.

The choice of identity for authentication does not affect the choice of identity for authorization. You might want to set up a common identity for authorization for administrative convenience, but authenticate each user to use that identity. The following procedure outlines the steps to authenticate individual users to use a common identity:

1. The IBM MQ administrator sets the MQTT channel identity to any name, such as `MQTTClientUser`, using IBM MQ Explorer.
2. The IBM MQ administrator authorizes `MQTTClient` to publish and subscribe to any topic:

   ```
    setmqaut -m QM1 -t q -n SYSTEM.MQTT.TRANSMIT.QUEUE -p MQTTClient -all +put
   setmqaut -m QM1 -t topic -n SYSTEM.BASE.TOPIC -p MQTTClient -all +pub +sub
   ```

3. The MQTT client application developer creates an MqttConnectOptions object and sets `Username` and `Password` before connecting to the server.
4. The security developer creates a JAAS LoginModule to authenticate the `Username` with the `Password` and includes it in the JAAS configuration file.

5. The IBM MQ administrator configures the MQTT channel to authenticate the `UserName` of the client using JAAS.

MQTT client authentication using SSL

Connections between the MQTT client and the queue manager are always initiated by the MQTT client. The MQTT client is always the SSL client. Client authentication of the server and server authentication of the MQTT client are both optional.

By providing the client with a private signed digital certificate, you can authenticate the MQTT client to WebSphere MQ. The WebSphere MQ Administrator can force MQTT clients to authenticate themselves to the queue manager using SSL. You can only request client authentication as part of mutual authentication.

As an alternative to using SSL, some kinds of Virtual Private Network (VPN), such as IPsec, authenticate the endpoints of a TCP/IP connection. VPN encrypts each IP packet that flows over the network. Once such a VPN connection is established, you have established a trusted network. You can connect MQTT clients to telemetry channels using TCP/IP over the VPN network.

Client authentication using SSL relies upon the client having a secret. The secret is the private key of the client in the case of a self-signed certificate, or a key provided by a certificate authority. The key is used to sign the digital certificate of the client. Anyone in possession of the corresponding public key can verify the digital certificate. Certificates can be trusted, or if they are chained, traced back through a certificate chain to a trusted root certificate. Client verification sends all the certificates in the certificate chain provided by the client to the server. The server checks the certificate chain until it finds a certificate it trusts. The trusted certificate is either the public certificate generated from a self-signed certificate, or a root certificate typically issued by a certificate authority. As a final, optional, step the trusted certificate can be compared with a "live" certificate revocation list.

The trusted certificate might be issued by a certificate authority and already included in the JRE certificate store. It might be a self-signed certificate, or any certificate that has been added to the telemetry channel keystore as a trusted certificate.

Note: The telemetry channel has a combined keystore/truststore that holds both the private keys to one or more telemetry channels, and any public certificates needed to authenticate clients. Because an SSL channel must have a keystore, and it is the same file as the channel truststore, the JRE certificate store is never referenced. The implication is that if authentication of a client requires a CA root certificate, you must place the root certificate in the keystore for the channel, even if the CA root certificate is already in the JRE certificate store. The JRE certificate store is never referenced.

Think about the threats that client authentication is intended to counter, and the roles the client and server play in countering the threats. Authenticating the client certificate alone is insufficient to prevent unauthorized access to a system. If someone else has got hold of the client device, the client device is not necessarily acting with the authority of the certificate holder. Never rely on a single defense against unwanted attacks. At least use a two-factor authentication approach and supplement possession of a certificate with knowledge of private information. For example, use JAAS, and authenticate the client using a password issued by the server.

The primary threat to the client certificate is that it gets into the wrong hands. The certificate is held in a password protected keystore at the client. How does it get placed in the keystore? How does the MQTT client get the password to the keystore? How secure is the password protection? Telemetry devices are often easy to remove, and then can be hacked in private. Must the device hardware be tamper-proof? Distributing and protecting client-side certificates is recognized to be hard; it is called the key-management problem.

A secondary threat is that the device is misused to access servers in unintended ways. For example, if the MQTT application is tampered with, it might be possible to use a weakness in the server configuration using the authenticated client identity.

To authenticate an MQTT client using SSL, configure the telemetry channel, and the client.

Related concepts:

"Telemetry channel configuration for MQTT client authentication using SSL"
The WebSphere MQ administrator configures telemetry channels at the server. Each channel is configured to accept a TCP/IP connection on a different port number. The channels are configured either as `com.ibm.mq.MQTT.channel/PlainText` or `com.ibm.mq.MQTT.channel/SSL`. SSL channels are configured with passphrase protected access to key files. If an SSL channel is defined with no passphrase or key file, the channel does not accept SSL connections.

Related information:

MQTT client configuration for client authentication using SSL

Telemetry channel configuration for MQTT client authentication using SSL:

The WebSphere MQ administrator configures telemetry channels at the server. Each channel is configured to accept a TCP/IP connection on a different port number. The channels are configured either as `com.ibm.mq.MQTT.channel/PlainText` or `com.ibm.mq.MQTT.channel/SSL`. SSL channels are configured with passphrase protected access to key files. If an SSL channel is defined with no passphrase or key file, the channel does not accept SSL connections.

Set the property, `com.ibm.mq.MQTT.ClientAuth` of an SSL telemetry channel to `REQUIRED` to force all clients connecting on that channel to provide proof that they have verified digital certificates. The client certificates are authenticated using certificates from certificate authorities, leading to a trusted root certificate. If the client certificate is self-signed, or is signed by a certificate that is from a certificate authority, the publicly signed certificates of the client, or certificate authority, must be stored securely at the server.

Place the publicly signed client certificate or the certificate from the certificate authority in the telemetry channel keystore. At the server, publicly signed certificates are stored in the same key file as privately signed certificates, rather than in a separate truststore.

The server verifies the signature of any client certificates it is sent using all the public certificates and cipher suites it has. The server verifies the key chain. The queue manager can be configured to test the certificate against the certificate revocation list. The queue manager revocation namelist property is `SSLCRLNL`.

If any of the certificates a client sends is verified by a certificate in the server keystore, then the client is authenticated.

The IBM MQ administrator can configure the same telemetry channel to use JAAS to check the `UserName` or `ClientIdentifier` of the client with the client `Password`.

You can use the same keystore for multiple telemetry channels.

Verification of at least one digital certificate in the password protected client keystore on the device authenticates the client to the server. The digital certificate is only used for authentication by IBM MQ. It is not used to verify the TCP/IP address of the client, set the identity of the client for authorization or accounting. The identity of the client adopted by the server is either the `Username` or `ClientIdentifier` of the client, or an identity created by the IBM MQ administrator.

You can also use SSL cipher suites for client authentication. If you plan to use SHA-2 cipher suites, see System requirements for using SHA-2 cipher suites with MQTT channels.

CipherSpecs and CipherSuites

Telemetry channel authentication using SSL

Connections between the MQTT client and the queue manager are always initiated by the MQTT client. The MQTT client is always the SSL client. Client authentication of the server and server authentication of the MQTT client are both optional.

The client always attempts to authenticate the server, unless the client is configured to use a CipherSpec that supports anonymous connection. If the authentication fails, then the connection is not established.

As an alternative to using SSL, some kinds of Virtual Private Network (VPN), such as IPsec, authenticate the endpoints of a TCP/IP connection. VPN encrypts each IP packet that flows over the network. Once such a VPN connection is established, you have established a trusted network. You can connect MQTT clients to telemetry channels using TCP/IP over the VPN network.

Server authentication using SSL authenticates the server to which you are about to send confidential information to. The client performs the checks matching the certificates sent from the server, against certificates placed in its truststore, or in its JRE `cacerts` store.

The JRE certificate store is a JKS file, `cacerts`. It is located in `JRE InstallPath\lib\security\`. It is installed with the default password `changeit`. You can either store certificates you trust in the JRE certificate store, or in the client truststore. You cannot use both stores. Use the client truststore if you want to keep the public certificates the client trusts separate from certificates other Java applications use. Use the JRE certificate store if you want to use a common certificate store for all Java applications running on the client. If you decide to use the JRE certificate store review the certificates it contains, to make sure you trust them.

You can modify the JSSE configuration by supplying a different trust provider. You can customize a trust provider to perform different checks on a certificate. In some OGSi environments that have used the MQTT client, the environment provides a different trust provider.

To authenticate the telemetry channel using SSL, configure the server, and the client.

Telemetry channel configuration for channel authentication using SSL

The WebSphere MQ administrator configures telemetry channels at the server. Each channel is configured to accept a TCP/IP connection on a different port number. The channels are configured either as `com.ibm.mq.MQTT.channel/PlainText` or `com.ibm.mq.MQTT.channel/SSL`. SSL channels are configured with passphrase protected access to key files. If an SSL channel is defined with no passphrase or key file, the channel does not accept SSL connections.

Store the digital certificate of the server, signed with its private key, in the keystore that the telemetry channel is going to use at the server. Store any certificates in its key chain in the keystore, if you want to transmit the key chain to the client. Configure the telemetry channel using IBM MQ explorer to use SSL. Provide it with the path to the keystore, and the passphrase to access the keystore. If you do not set the TCP/IP port number of the channel, the SSL telemetry channel port number defaults to 8883.

You can also use SSL cipher suites for channel authentication. If you plan to use SHA-2 cipher suites, see System requirements for using SHA-2 cipher suites with MQTT channels.

DEFINE CHANNEL (MQTT)

ALTER CHANNEL (MQTT)

CipherSpecs and CipherSuites

Publication privacy on telemetry channels

The privacy of MQTT publications sent in either direction across telemetry channels is secured by using SSL to encrypt transmissions over the connection.

MQTT clients that connect to telemetry channels use SSL to secure the privacy of publications transmitted on the channel using symmetric key cryptography. Because the endpoints are not authenticated, you cannot trust channel encryption alone. Combine securing privacy with server or mutual authentication.

As an alternative to using SSL, some kinds of Virtual Private Network (VPN), such as IPsec, authenticate the endpoints of a TCP/IP connection. VPN encrypts each IP packet that flows over the network. Once such a VPN connection is established, you have established a trusted network. You can connect MQTT clients to telemetry channels using TCP/IP over the VPN network.

For a typical configuration, which encrypts the channel and authenticates the server, consult "Telemetry channel authentication using SSL" on page 157.

Encrypting SSL connections without authenticating the server exposes the connection to man-in-the-middle attacks. Although the information you exchange is protected against eavesdropping, you do not know who you are exchanging it with. Unless you control the network, you are exposed to someone intercepting your IP transmissions, and masquerading as the endpoint.

You can create an encrypted SSL connection, without authenticating the server, by using a Diffie-Hellman key exchange CipherSpec that supports anonymous SSL. The master secret, shared between the client and server, and used to encrypt SSL transmissions, is established without exchanging a privately signed server certificate.

Because anonymous connections are insecure, most SSL implementations do not default to using anonymous CipherSpecs. If a client request for SSL connection is accepted by a telemetry channel, the channel must have a keystore protected by a passphrase. By default, since SSL implementations do not use anonymous CipherSpecs, the keystore must contain a privately signed certificate that the client can authenticate.

If you use anonymous CipherSpecs, the server keystore must exist, but it need not contain any privately signed certificates.

Another way to establish an encrypted connection is to replace the trust provider at the client with your own implementation. Your trust provider would not authenticate the server certificate, but the connection would be encrypted.

SSL configuration of MQTT Java clients and telemetry channels

Configure SSL to authenticate the telemetry channel and the MQTT Java client, and encrypt the transfer of messages between them. MQTT Java clients use Java Secure Socket Extension (JSSE) to connect telemetry channels using SSL. As an alternative to using SSL, some kinds of Virtual Private Network (VPN), such as IPsec, authenticate the endpoints of a TCP/IP connection. VPN encrypts each IP packet that flows over the network. Once such a VPN connection is established, you have established a trusted network. You can connect MQTT clients to telemetry channels using TCP/IP over the VPN network.

You can configure the connection between a Java MQTT client and a telemetry channel to use the SSL protocol over TCP/IP. What is secured depends on how you configure SSL to use JSSE. Starting with the most secured configuration, you can configure three different levels of security:

1. Permit only trusted MQTT clients to connect. Connect an MQTT client only to a trusted telemetry channel. Encrypt messages between the client and the queue manager; see “MQTT client authentication using SSL” on page 155
2. Connect an MQTT client only to a trusted telemetry channel. Encrypt messages between the client and the queue manager; see “Telemetry channel authentication using SSL” on page 157.
3. Encrypt messages between the client and the queue manager; see “Publication privacy on telemetry channels” on page 158.

JSSE configuration parameters

Modify JSSE parameters to alter the way an SSL connection is configured. The JSSE configuration parameters are arranged into three sets:

1. IBM MQ Telemetry channel
2. MQTT Java client
3. JRE

Configure the telemetry channel parameters using IBM MQ Explorer. Set the MQTT Java Client parameters in the MqttConnectionOptions.SSLProperties attribute. Modify JRE security parameters by editing files in the JRE security directory on both the client and server.

IBM MQ Telemetry channel

Set all the telemetry channel SSL parameters using IBM MQ Explorer.

`ChannelName`

`ChannelName` is a required parameter on all channels.

The channel name identifies the channel associated with a particular port number. Name channels to help you administer sets of MQTT clients.

`PortNumber`

PortNumber is an optional parameter on all channels. It defaults to 1883 for TCP channels, and 8883 for SSL channels.

The TCP/IP port number associated with this channel. MQTT clients are connected to a channel by specifying the port defined for the channel. If the channel has SSL properties, the client must connect using the SSL protocol; for example:

```
MQTTClient mqttClient = new MqttClient( "ssl://www.example.org:8884", "clientId1");
mqttClient.connect();
```

KeyFileName

KeyFileName is a required parameter for SSL channels. It must be omitted for TCP channels.

KeyFileName is the path to the Java keystore containing digital certificates that you provide. Use JKS, JCEKS or PKCS12 as the type of keystore on the server.

Identify the keystore type by using one of the following file extensions:

- .jks
- .jceks
- .p12
- .pkcs12

A keystore with any other file extension is assumed to be a JKS keystore.

You can combine one type of keystore at the server with other types of keystore at the client.

Place the private certificate of the server in the keystore. The certificate is known as the server certificate. The certificate can be self-signed, or part of a certificate chain that is signed by a signing authority.

If you are using a certificate chain, place the associated certificates in the server keystore.

The server certificate, and any certificates in its certificate chain, are sent to clients to authenticate the identity of the server.

If you have set ClientAuth to Required, the keystore must contain any certificates necessary to authenticate the client. The client sends a self-signed certificate, or a certificate chain, and the client is authenticated by the first verification of this material against a certificate in the keystore. Using a certificate chain, one certificate can verify many clients, even if they are issued with different client certificates.

PassPhrase

PassPhrase is a required parameter for SSL channels. It must be omitted for TCP channels.

The passphrase is used to protect the keystore.

ClientAuth

ClientAuth is an optional SSL parameter. It defaults to no client authentication. It must be omitted for TCP channels.

Set ClientAuth if you want the telemetry (MQXR) service to authenticate the client, before permitting the client to connect to the telemetry channel.

If you set ClientAuth, the client must connect to the server using SSL, and authenticate the server. In response to setting ClientAuth, the client sends its digital certificate to the server, and any other certificates in its keystore. Its digital certificate is known as the client certificate. These certificates are authenticated against certificates held in the channel keystore, and in the JRE cacerts store.

CipherSuite

CipherSuite is an optional SSL parameter. It defaults to try all the enabled CipherSpecs. It must be omitted for TCP channels.

If you want to use a particular CipherSpec, set CipherSuite to the name of the CipherSpec that must be used to establish the SSL connection.

The telemetry service and MQTT client negotiate a common CipherSpec from all the CipherSpecs that are enabled at each end. If a specific CipherSpec is specified at either or both ends of the connection, it must match the CipherSpec at the other end.

Install additional ciphers by adding additional providers to JSSE.

Federal Information Processing Standards (FIPS)

FIPS is an optional setting. By default it is not set.

Either in the properties panel of the queue manager, or using **runmqsc**, set SSLFIPS. SSLFIPS specifies whether only FIPS-certified algorithms are to be used.

Revocation namelist

Revocation namelist is an optional setting. By default it is not set.

Either in the properties panel of the queue manager, or using **runmqsc**, set SSLCRLNL. SSLCRLNL specifies a namelist of authentication information objects which are used to provide certificate revocation locations.

No other queue manager parameters that set SSL properties are used.

MQTT Java client

Set SSL properties for the Java client in MqttConnectionOptions.SSLProperties ; for example:

```
java.util.Properties sslClientProperties = new Properties();
sslClientProperties.setProperty("com.ibm.ssl.keyStoreType", "JKS");
com.ibm.micro.client.mqttv3.MqttConnectOptions conOptions = new MqttConnectOptions();
conOptions.setSSLProperties(sslClientProperties);
```

The names and values of specific properties are described in the MqttConnectOptions class. For links to client API documentation for the MQTT client libraries, see MQTT client programming reference.

Protocol

Protocol is optional.

The protocol is selected in negotiation with the telemetry server. If you require a specific protocol you can select one. If the telemetry server does not support the protocol the connection fails.

ContextProvider

ContextProvider is optional.

KeyStore

KeyStore is optional. Configure it if ClientAuth is set at the server to force authentication of the client.

Place the digital certificate of the client, signed using its private key, into the keystore. Specify the keystore path and password. The type and provider are optional. JKS is the default type, and IBMJCE is the default provider.

Specify a different keystore provider to reference a class that adds a new keystore provider. Pass the name of the algorithm used by the keystore provider to instantiate the KeyManagerFactory by setting the key manager name.

TrustStore

TrustStore is optional. You can place all the certificates you trust in the JRE cacerts store.

Configure the truststore if you want to have a different truststore for the client. You might not configure the truststore if the server is using a certificate issued by a well known CA that already has its root certificate stored in cacerts.

Add the publicly signed certificate of the server or the root certificate to the truststore, and specify the truststore path and password. JKS is the default type, and IBMJCE is the default provider.

Specify a different truststore provider to reference a class that adds a new truststore provider. Pass the name of the algorithm used by the truststore provider to instantiate the TrustManagerFactory by setting the trust manager name.

JRE

Other aspects of Java security that affect the behavior of SSL on both the client and server are configured in the JRE. The configuration files on Windows are in *Java Installation Directory*\jre\lib\security. If you are using the JRE shipped with IBM MQ the path is as shown in the following table:

Table 4. Filepaths by platform for JRE SSL configuration files

Platform	Filepath
Windows	*WMQ Installation Directory*\java\jre\lib\security
Linux for System x 32 bit	*WMQ Installation Directory*/java/jre/lib/security
Other UNIX and Linux platforms	*WMQ Installation Directory*/java/jre64/jre/lib/security

Well-known certificate authorities

The cacerts file contains the root certificates of well-known certificate authorities. The cacerts is used by default, unless you specify a truststore. If you use the cacerts store, or do not provide a truststore, you must review and edit the list of signers in cacerts to meet your security requirements.

You can open cacerts using the IBM MQ command strmqikm.which runs the IBM Key Management utility. Open cacerts as a JKS file, using the password changeit. Modify the password to secure the file.

Configuring security classes

Use the java.security file to register additional security providers and other default security properties.

Permissions

Use the java.policy file to modify the permissions granted to resources. javaws.policy grants permissions to javaws.jar

Encryption strength

Some JREs ship with reduced strength encryption. If you cannot import keys into keystores, reduced strength encryption might be the cause. Either, try starting **ikeyman** using the **strmqikm** command, or download strong, but limited jurisdiction files from IBM developer kits, Security information.

Important: Your country of origin might have restrictions on the import, possession, use, or re-export to another country, of encryption software. Before downloading or using the unrestricted policy files, you must check the laws of your country. Check its regulations, and its policies concerning the import, possession, use, and re-export of encryption software, to determine if it is permitted.

Modify the trust provider to permit the client to connect to any server

The example illustrates how to add a trust provider and reference it from the MQTT client code. The example performs no authentication of the client or server. The resulting SSL connection is encrypted without being authenticated.

The code snippet in Figure 24 sets the AcceptAllProviders trust provider and trust manager for the MQTT client.

```
java.security.Security.addProvider(new AcceptAllProvider());
java.util.Properties sslClientProperties = new Properties();
sslClientProperties.setProperty("com.ibm.ssl.trustManager","TrustAllCertificates");
sslClientProperties.setProperty("com.ibm.ssl.trustStoreProvider","AcceptAllProvider");
conOptions.setSSLProperties(sslClientProperties);
```

Figure 24. MQTT Client code snippet

```
package com.ibm.mq.id;
public class AcceptAllProvider extends java.security.Provider {
private static final long serialVersionUID = 1L;
public AcceptAllProvider() {
super("AcceptAllProvider", 1.0, "Trust all X509 certificates");
put("TrustManagerFactory.TrustAllCertificates",
AcceptAllTrustManagerFactory.class.getName());
}
```

Figure 25. AcceptAllProvider.java

```
protected static class AcceptAllTrustManagerFactory extends
javax.net.ssl.TrustManagerFactorySpi {
public AcceptAllTrustManagerFactory() {}
protected void engineInit(java.security.KeyStore keystore) {}
protected void engineInit(
javax.net.ssl.ManagerFactoryParameters parameters) {}
protected javax.net.ssl.TrustManager[] engineGetTrustManagers() {
return new javax.net.ssl.TrustManager[] { new AcceptAllX509TrustManager() };
}
```

Figure 26. AcceptAllTrustManagerFactory.java

```
protected static class AcceptAllX509TrustManager implements
javax.net.ssl.X509TrustManager {
public void checkClientTrusted(
java.security.cert.X509Certificate[] certificateChain,
String authType) throws java.security.cert.CertificateException {
report("Client authtype=" + authType);
for (java.security.cert.X509Certificate certificate : certificateChain) {
report("Accepting:" + certificate);
}
}
public void checkServerTrusted(
java.security.cert.X509Certificate[] certificateChain,
String authType) throws java.security.cert.CertificateException {
report("Server authtype=" + authType);
for (java.security.cert.X509Certificate certificate : certificateChain) {
report("Accepting:" + certificate);
}
}
public java.security.cert.X509Certificate[] getAcceptedIssuers() {
return new java.security.cert.X509Certificate[0];
}
private static void report(String string) {
System.out.println(string);
}
}
```

Figure 27. AcceptAllX509TrustManager.java

Telemetry channel JAAS configuration

Configure JAAS to authenticate the `Username` sent by the client.

The IBM MQ administrator configures which MQTT channels require client authentication using JAAS. Specify the name of a JAAS configuration for each channel that is to perform JAAS authentication. Channels can all use the same JAAS configuration, or they can use different JAAS configurations. The configurations are defined in *WMQData directory*\qmgrs*qMgrName*\mqxr\jaas.config.

The `jaas.config` file is organized by JAAS configuration name. Under each configuration name is a list of Login configurations; see Figure 28 on page 165.

JAAS provides four standard Login modules. The standard NT and UNIX Login modules are of limited value.

JndiLoginModule
Authenticates against a directory service configured under JNDI (Java Naming and Directory Interface).

Krb5LoginModule
Authenticates using Kerberos protocols.

NTLoginModule
Authenticates using the NT security information for the current user.

UnixLoginModule
Authenticates using the UNIX security information for the current user.

The problem with using `NTLoginModule` or `UnixLoginModule` is that the telemetry (MQXR) service runs with the `mqm` identity, and not the identity of the MQTT channel. `mqm` is the identity passed to `NTLoginModule` or `UnixLoginModule` for authentication, and not the identity of the client.

To overcome this problem, write your own Login module, or use the other standard Login modules. A sample `JAASLoginModule.java` is supplied with IBM MQ Telemetry. It is an implementation of the `javax.security.auth.spi.LoginModule` interface. Use it to develop your own authentication method.

Any new LoginModule classes you provide must be on the class path of the telemetry (MQXR) service. Do not place your classes in IBM MQ directories that are in the class path. Create your own directories, and define the whole class path for the telemetry (MQXR) service.

You can augment the class path used by the telemetry (MQXR) service by setting class path in the `service.env` file. `CLASSPATH` must be capitalized, and the class path statement can only contain literals. You cannot use variables in the CLASSPATH; for example `CLASSPATH=%CLASSPATH%` is incorrect. The telemetry (MQXR) service sets its own classpath. The CLASSPATH defined in `service.env` is added to it.

The telemetry (MQXR) service provides two callbacks that return the `Username` and the `Password` for a client connected to the MQTT channel. The `Username` and `Password` are set in the MqttConnectOptions object. See Figure 29 on page 166 for an example of how to access `Username` and `Password`.

Examples

An example of a JAAS configuration file with one named configuration, `MQXRConfig`.

```
MQXRConfig {
samples.JAASLoginModule required debug=true;
//com.ibm.security.auth.module.NTLoginModule required;
//com.ibm.security.auth.module.Krb5LoginModule required
//         principal=principal@your_realm
//         useDefaultCcache=TRUE
//         renewTGT=true;
//com.sun.security.auth.module.NTLoginModule required;
//com.sun.security.auth.module.UnixLoginModule required;
//com.sun.security.auth.module.Krb5LoginModule required
//         useTicketCache="true"
//         ticketCache="${user.home}${/}tickets";
};
```

Figure 28. Sample `jaas.config` file

An example of a JAAS Login module coded to receive the `Username` and `Password` provided by an MQTT client.

```
public boolean login()
throws javax.security.auth.login.LoginException {
javax.security.auth.callback.Callback[] callbacks =
new javax.security.auth.callback.Callback[2];
callbacks[0] = new javax.security.auth.callback.NameCallback("NameCallback");
callbacks[1] = new javax.security.auth.callback.PasswordCallback(
"PasswordCallback", false);
try {
callbackHandler.handle(callbacks);
String username = ((javax.security.auth.callback.NameCallback) callbacks[0])
.getName();
char[] password = ((javax.security.auth.callback.PasswordCallback) callbacks[1])
.getPassword(); // Accept everything.
if (true) {
loggedIn = true;
} else
throw new javax.security.auth.login.FailedLoginException("Login failed");

principal= new JAASPrincipal(username);

} catch (java.io.IOException exception) {
throw new javax.security.auth.login.LoginException(exception.toString());
} catch (javax.security.auth.callback.UnsupportedCallbackException exception) {
throw new javax.security.auth.login.LoginException(exception.toString());
}

return loggedIn;
}
```

Figure 29. Sample JAASLoginModule.Login() method

Administering IBM MQ Light

V 8.0.0.4

You can administer MQ Light using MQ Explorer or at a command line. Use the Explorer to configure channels and monitor the MQ Light clients that are connected to IBM MQ. Configure the security of MQ Light using TLS and JAAS.

Before you start

For information about installing AMQP on your platform, see Choosing what to install. Install the AMQP Service component by using the IBM MQ V8.0.0.4 manufacturing refresh, not the V8.0.0.4 Fix Pack. You cannot install the AMQP component on a version of the queue manager earlier than V8.0.0.4.

Administering using MQ Explorer

Use the Explorer to configure AMQP channels and monitor the MQ Light clients that are connected to IBM MQ. You can configure the security of MQ Light using TLS and JAAS.

Administering using the command line

You can administer MQ Light at the command line using the IBM MQ MQSC commands.

Viewing IBM MQ objects in use by MQ Light clients

V 8.0.0.4

You can view the different IBM MQ resources in use by MQ Light clients, for example connections and subscriptions.

Connections

When the AMQP service is started new Hconns are created and connected to the queue manager. This pool of Hconns is used when MQ Light clients publish messages. You can view the Hconns by using the **DISPLAY CONN** command. For example:

```
DISPLAY CONN(*) TYPE(CONN) WHERE (APPLDESC LK 'WebSphere MQ Advanced Message Queuing Protocol*')
```

This command also shows any client-specific Hconns. The Hconns that have a blank client ID attribute are the Hconns used in the pool

When an MQ Light client connects to an AMQP channel, a new Hconn is connected to the queue manager. This Hconn is used to consume messages asynchronously for the subscriptions that the MQ Light client has created. You can view the Hconn used by a particular MQ Light client using the **DISPLAY CONN** command. For example:

```
DISPLAY CONN(*) TYPE(CONN) WHERE (CLIENTID EQ 'recv_abcd1234')
```

Subscriptions created by clients

When an MQ Light client subscribes to a topic, a new IBM MQ subscription is created. The subscription name includes the following information:

- The name of the client. If the client joined a shared subscription, the name of the share is used
- The topic pattern that the client subscribed to
- A prefix. The prefix is `private` if the client created a non-shared subscription, or `share` if the client joined a shared subscription

To view the subscriptions in use by a particular MQ Light client, run the **DISPLAY SUB** command and filter on the `private` prefix:

```
DISPLAY SUB(':private:*')
```

To view the shared subscriptions that are in use by multiple clients, run the **DISPLAY SUB** command and filter on the `share` prefix:

```
DISPLAY SUB(':share:*')
```

Because shared subscriptions can be used by multiple MQ Light clients, you might want to view the clients currently consuming messages from the shared subscription. You can do this by listing the Hconns that currently have a handle open on the subscription queue. To view the clients currently using a share, complete the following steps:

1. Find the queue name that the shared subscription uses as a destination. For example:

   ```
   DISPLAY SUB(':private:recv_e298452:public') DEST
      5 : DISPLAY SUB(':private:recv_e298452:public') DEST
   AMQ8096: WebSphere MQ subscription inquired.
      SUBID(414D5120514D31202020202020202020707E0A565C2D0020)
      SUB(:private:recv_e298452:public)
      DEST(SYSTEM.MANAGED.DURABLE.560A7E7020002D5B)
   ```

2. Run the **DISPLAY CONN** command to find the handles open on that queue:

   ```
   DISPLAY CONN(*) TYPE(HANDLE) WHERE  (OBJNAME
   EQ SYSTEM.MANAGED.DURABLE.560A7E7020002D5B)
      21 : DISPLAY CONN(*) TYPE(HANDLE) WHERE(OBJNAME EQ
   ```

```
SYSTEM.MANAGED.DURABLE.560A7E7020002D5B)

AMQ8276: Display Connection details.
   CONN(707E0A56642B0020)
   EXTCONN(414D5143514D3120202020202020202020)
   TYPE(HANDLE)

   OBJNAME(SYSTEM.BASE.TOPIC)      OBJTYPE(TOPIC)

   OBJNAME(SYSTEM.MANAGED.DURABLE.560A7E7020002961)
   OBJTYPE(QUEUE)
```

3. For each of the handles, view the MQ Light client ID that has the handle open:

```
DISPLAY CONN(707E0A56642B0020) CLIENTID
   23 : DISPLAY CONN(707E0A56642B0020) CLIENTID

AMQ8276: Display Connection details.
   CONN(707E0A56642B0020)
   EXTCONN(414D5143514D3120202020202020202020)
   TYPE(CONN)
   CLIENTID(recv_8f02c9d)
DISPLAY CONN(707E0A565F290020) CLIENTID
   24 : DISPLAY CONN(707E0A565F290020) CLIENTID
AMQ8276: Display Connection details.
   CONN(707E0A565F290020)
   EXTCONN(414D5143514D3120202020202020202020)
   TYPE(CONN)
   CLIENTID(recv_86d8888)
```

MQ Light client identification, authorization, and authentication

V 8.0.0.4

Like other IBM MQ client applications, you can secure AMQP connections in a number of ways.

You can use the following security features to secure AMQP connections to IBM MQ:
- Channel authentication records
- Connection authentication
- Channel MCA user configuration
- IBM MQ authority definitions
- TLS connectivity

From a security perspective, establishing a connection consists of the following two steps:
- Deciding whether the connection should continue
- Deciding which IBM MQ identity the application assumes for later authority checks

The following information outlines different IBM MQ configurations and the steps that are worked through when an AMQP client tries to make a connection. Not all IBM MQ configurations use all of the steps described. For example, some configurations do not use TLS for connections inside the company firewall and some configurations use TLS but do not use client certificates for authentication. Many environments do not use custom or custom JAAS modules.

Establishing a connection

The following steps describe what happens when a connection is being established by an AMQP client. The steps determine whether the connection continues and which IBM MQ identity the application assumes for authority checks:

1. If the client opens a TLS connection to IBM MQ and provides a certificate, the queue manager attempts to validate the client certificate.

2. If the client provides user name and password credentials, an AMQP SASL frame is received by the queue manager and MQ CONNAUTH configuration is checked.
3. MQ channel authentication rules are checked (for example, whether the IP address and TLS certificate DN are valid)
4. Channel MCAUSER is asserted, unless channel authentication rules determine otherwise.
5. If a JAAS module has been configured, it is invoked
6. MQ CONNECT authority check applied to resulting MQ user ID.
7. Connection established with an assumed IBM MQ identity.

Publishing a message

The following steps describe what happens when a message is being published by an AMQP client. The steps determine whether the connection continues and which IBM MQ identity the application assumes for authority checks:

1. AMQP link attach frame arrives at queue manager. IBM MQ publish authority for the specified topic string is checked for the MQ user identity established during connection.
2. Message is published to specified topic string.

Subscribing to a topic pattern

The following steps describe what happens when an AMQP client subscribes to a topic pattern. The steps determine whether the connection continues and which IBM MQ identity the application assumes for authority checks:

1. AMQP link attach frame arrives at queue manager. IBM MQ subscribe authority for the specified topic pattern is checked for the MQ user identity established during connection.
2. Subscription is created.

MQ Light client identity and authorization

V 8.0.0.4

Use the MQ Light client ID, the MQ Light user name, or a common client identity defined on the channel or in a channel authentication rule, for authorization to access IBM MQ objects.

The administrator makes the choice when defining or modifying the AMQP channel, by configuring the queue manager CONNAUTH setting, or by defining channel authentication rules. The identity is used to authorize access to IBM MQ topics. The choice is made based on the following:

1. The channel USECLNTID attribute.
2. The ADOPTCTX attribute of the queue manager CONNAUTH rule.
3. The MCAUSER attribute defined on the channel.
4. The USERSRC attribute of a matching channel authentication rule.

Avoid trouble: The identity chosen by this process is thereafter referred to, for example by the DISPLAY CHSTATUS (AMQP) command, as the MCAUSER of the client. Be aware that this is not necessarily the same identity as the MCAUSER of the channel that is referred to in choice (2).

Use the IBM MQ **setmqaut** command to select which objects, and which actions, are authorized to be used by the identity associated with the AMQP channel. For example, the following commands authorize a channel identity `AMQPClient`, provided by the administrator of queue manager `QM1`:

```
setmqaut -m QM1 -t topic -n SYSTEM.BASE.TOPIC -p AMQPClient -all +pub +sub
```

and

```
setmqaut -m QM1 -t qmgr -p AMQPClient -all +connect
```

MQ Light client authentication using a password

V 8.0.0.4

Authenticate the MQ Light user name using the client password. You can authenticate the client using a different identity from the identity used to authorize the client to publish and subscribe to topics.

The AMQP service can use MQ CONNAUTH or JAAS to authenticate the client user name. If one of these is configured, the password provided by the client is verified by the MQ CONNAUTH configuration or the JAAS module.

The following procedure outlines example steps to authenticate individual users against the local OS users and passwords and, if successful, adopt the common identity `AMQPUser`:

1. The IBM MQ administrator sets the AMQP channel MCAUSER identity to any name, such as `AMQPUser`, using IBM MQ Explorer.
2. The IBM MQ administrator authorizes `AMQPUser` to publish and subscribe to any topic:
   ```
   setmqaut -m QM1 -t topic -n SYSTEM.BASE.TOPIC -p AMQPUser -all +pub +sub +connect
   ```
3. The IBM MQ administrator configures an IDPWOS CONNAUTH rule to check the user name and password presented by the client. The CONNAUTH rule should set CHCKCLNT(REQUIRED) and ADOPTCTX(NO).

Note: You are recommended to use channel authentication rules and to set the MCAUSER channel attribute to a user who has no privileges, to allow more control over connections to the queue manager.

Publication privacy on channels

V 8.0.0.4

The privacy of AMQP publications sent in either direction across AMQP channels is secured by using TLS to encrypt transmissions over the connection.

AMQP clients that connect to AMQP channels use TLS to secure the privacy of publications transmitted on the channel using symmetric key cryptography. Because the endpoints are not authenticated, you cannot trust channel encryption alone. Combine securing privacy with server or mutual authentication.

As an alternative to using TLS, some kinds of Virtual Private Network (VPN), such as IPsec, authenticate the endpoints of a TCP/IP connection. VPN encrypts each IP packet that flows over the network. Once such a VPN connection is established, you have established a trusted network. You can connect AMQP clients to AMQP channels using TCP/IP over the VPN network.

Encrypting TLS connections without authenticating the server exposes the connection to man-in-the-middle attacks. Although the information you exchange is protected against eavesdropping, you do not know who you are exchanging it with. Unless you control the network, you are exposed to someone intercepting your IP transmissions, and masquerading as the endpoint.

You can create an encrypted TLS connection, without authenticating the server, by using a Diffie-Hellman key exchange CipherSpec that supports anonymous TLS. The master secret, shared between the client and server, and used to encrypt TLS transmissions, is established without exchanging a privately signed server certificate.

Because anonymous connections are insecure, most TLS implementations do not default to using anonymous CipherSpecs. If a client request for TLS connection is accepted by an AMQP channel, the channel must have a keystore protected by a passphrase. By default, since TLS implementations do not use anonymous CipherSpecs, the keystore must contain a privately signed certificate that the client can authenticate.

If you use anonymous CipherSpecs, the server keystore must exist, but it need not contain any privately signed certificates.

Another way to establish an encrypted connection is to replace the trust provider at the client with your own implementation. Your trust provider would not authenticate the server certificate, but the connection would be encrypted.

Configuring MQ Light clients with TLS

V 8.0.0.4

You can configure MQ Light clients to use TLS to protect data flowing across the network and to authenticate the identity of the queue manager the client connects to.

To use TLS for the connection from an MQ Light client to an AMQP channel, you must ensure the queue manager has been configured to TLS. Configuring SSL on queue managers describes how to configure the keystore that a queue manager reads TLS certificates from.

When the queue manager has been configured with a keystore, you must configure the TLS attributes on the AMQP channel that clients will connect to. AMQP channels have four attributes related to TLS configuration as follows:

SSLCAUTH
The SSLCAUTH attribute is used to specify whether the queue manager should require an MQ Light client to present a client certificate to verify its identity.

SSLCIPH
The SSLCIPH attribute specifies the cipher the channel should use to encode data in the TLS flow.

SSLPEER
The SSLPEER attribute is used to specify the distinguished name (DN) a client certificate must match if a connection is to be allowed.

CERTLABL
The CERTLABL specifies the certificate the queue manager should present to the client. The queue manager's keystore can contain multiple certificates. This attribute allows you to specify the certificate to be used for connections to this channel. If no CERTLABL is specified the IBM MQ default certificate ibmwebspheremq*qmgr-name* is used.

When you have configured your AMQP channel with the TLS attributes, you must restart the AMQP service using the following command:

```
STOP SERVICE(SYSTEM.AMQP.SERVICE) START SERVICE(SYSTEM.AMQP.SERVICE)
```

When an MQ Light client connects to an AMQP channel protected by TLS, the client verifies the identity of the certificate presented by the queue manager. To do this you must configure your MQ Light client with a truststore containing the queue manager's certificate. The steps to do this vary depending on the MQ Light client you are using.

- For the MQ Light client for Node JS API documentation, see https://www.npmjs.com/package/mqlight
- For the MQ Light client for Java API documentation, see http://mqlight.github.io/java-mqlight/
- For the MQ Light client for Ruby documentation, see http://www.rubydoc.info/github/mqlight/ruby-mqlight/
- For the MQ Light client for Python documentation, see http://python-mqlight.readthedocs.org/en/latest/

Disconnecting MQ Light clients from the queue manager

V 8.0.0.4

If you want to disconnect MQ Light from the queue manager, either run the PURGE CHANNEL command or stop the connection to the MQ Light client.

- Run the **PURGE CHANNEL** command. For example:

  ```
  PURGE CHANNEL(MYAMQP) CLIENTID('recv_28dbb7e')
  ```

- Alternatively, stop the connection that the MQ Light client is using to disconnect the client by completing the following steps:

  1. Find the connection that the client is using by running the **DISPLAY CONN** command. For example:

     ```
     DISPLAY CONN(*) TYPE(CONN) WHERE (CLIENTID EQ 'recv_28dbb7e')
     ```

     The command output is as follows:

     ```
     DISPLAY CONN(*)  TYPE(CONN) WHERE(CLIENTID EQ 'recv_28dbb7e')
       40 : DISPLAY CONN(*) TYPE(CONN) WHERE(CLIENTID EQ 'recv_28dbb7e')
     AMQ8276: Display  Connection details.
       CONN(707E0A565F2D0020)
       EXTCONN(414D5143514D31202020202020202020)
       TYPE(CONN)
       CLIENTID(recv_28dbb7e)
     ```

  2. Stop the connection. For example:

     ```
     STOP CONN(707E0A565F2D0020)
     ```

Administering multicast

Use this information to learn about the IBM MQ Multicast administration tasks such as reducing the size of multicast messages and enabling data conversion.

Getting started with multicast

Use this information to get started with IBM MQ Multicast topics and communication information objects.

About this task

IBM MQ Multicast messaging uses the network to deliver messages by mapping topics to group addresses. The following tasks are a quick way to test if the required IP address and port are correctly configured for multicast messaging.

Creating a COMMINFO object for multicast

The communication information (COMMINFO) object contains the attributes associated with multicast transmission. For more information about the COMMINFO object parameters, see DEFINE COMMINFO.

Use the following command-line example to define a COMMINFO object for multicast:

```
DEFINE COMMINFO(MC1) GRPADDR(group address) PORT(port number)
```

where *MC1* is the name of your COMMINFO object, *group address* is your group multicast IP address or DNS name, and the *port number* is the port to transmit on (The default value is 1414).

A new COMMINFO object called *MC1* is created; This name is the name that you must specify when defining a TOPIC object in the next example.

Creating a TOPIC object for multicast

A topic is the subject of the information that is published in a publish/subscribe message, and a topic is defined by creating a TOPIC object. TOPIC objects have two parameters which define whether they can be used with multicast or not. These parameters are: **COMMINFO** and **MCAST**.

- **COMMINFO** This parameter specifies the name of the multicast communication information object. For more information about the COMMINFO object parameters, see DEFINE COMMINFO.
- **MCAST** This parameter specifies whether multicast is allowable at this position in the topic tree.

Use the following command-line example to define a TOPIC object for multicast:

```
DEFINE TOPIC(ALLSPORTS) TOPICSTR('Sports') COMMINFO(MC1) MCAST(ENABLED)
```

A new TOPIC object called *ALLSPORTS* is created. It has a topic string *Sports*, its related communication information object is called *MC1* (which is the name you specified when defining a COMMINFO object in the previous example), and multicast is enabled.

Testing the multicast publish/subscribe

After the TOPIC and COMMINFO objects have been created, they can be tested using the `amqspubc` sample and the `amqssubc` sample. For more information about these samples see The Publish/Subscribe sample programs.

1. Open two command-line windows; The first command line is for the `amqspubc` publish sample, and the second command line is for the `amqssubc` subscribe sample.
2. Enter the following command at command line 1:
   ```
   amqspubc Sports QM1
   ```
   where *Sports* is the topic string of the TOPIC object defined in an earlier example, and *QM1* is the name of the queue manager.
3. Enter the following command at command line 2:
   ```
   amqssubc Sports QM1
   ```
   where *Sports* and *QM1* are the same as used in step 2.
4. Enter `Hello world` at command line 1. If the port and IP address that are specified in the COMMINFO object are configured correctly; the `amqssubc` sample, which is listening on the port for publications from the specified address, outputs `Hello world` at command line 2.

IBM MQ Multicast topic topology

Use this example to understand the IBM MQ Multicast topic topology.

IBM MQ Multicast support requires that each subtree has its own multicast group and data stream within the total hierarchy.

The *classful network* IP addressing scheme has designated address space for multicast address. The full multicast range of IP address is `224.0.0.0` to `239.255.255.255`, but some of these addresses are reserved. For a list of reserved address either contact your system administrator or see http://www.iana.org/assignments/multicast-addresses for more information. It is recommended that you use the locally scoped multicast address in the range of `239.0.0.0` to `239.255.255.255`.

In the following diagram, there are two possible multicast data streams:

```
DEF COMMINFO(MC1) GRPADDR(239.XXX.XXX.XXX
)

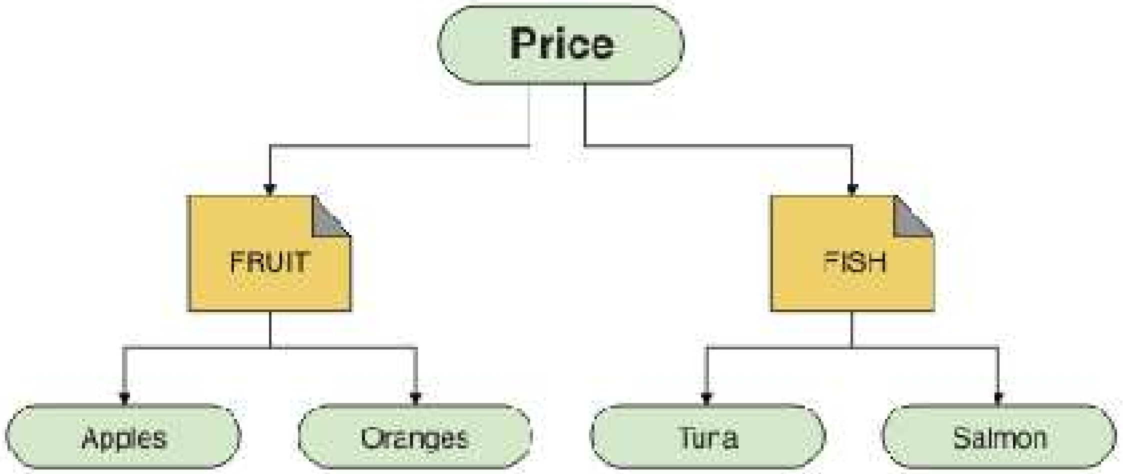
DEF COMMINFO(MC2) GRPADDR(239.YYY.YYY.YYY)
```

where *239.XXX.XXX.XXX* and *239.YYY.YYY.YYY* are valid multicast addresses.

These topic definitions are used to create a topic tree as shown in the following diagram:

```
DEFINE TOPIC(FRUIT) TOPICSTRING('Price/FRUIT') MCAST(ENABLED) COMMINFO(MC1)

DEFINE TOPIC(FISH) TOPICSTRING('Price/FISH') MCAST(ENABLED) COMMINFO(MC2)
```



Each multicast communication information (COMMINFO) object represents a different stream of data because their group addresses are different. In this example, the `FRUIT` topic is defined to use COMMINFO object `MC1`, the `FISH` topic is defined to use COMMINFO object `MC2`, and the `Price` node has no multicast definitions.

IBM MQ Multicast has a 255 character limit for topic strings. This limitation means that care must be taken with the names of nodes and leaf-nodes within the tree; if the names of nodes and leaf-nodes are too long, the topic string might exceed 255 characters and return the 2425 (0979) (RC2425): MQRC_TOPIC_STRING_ERROR reason code. It is recommended to make topic strings as short as possible because longer topic strings might have a detrimental effect on performance.

Controlling the size of multicast messages

Use this information to learn about the IBM MQ message format, and reduce the size of IBM MQ messages.

IBM MQ messages have a number of attributes associated with them which are contained in the message descriptor. For small messages, these attributes might represent most of the data traffic and can have a significant detrimental effect on the transmission rate. IBM MQ Multicast enables the user to configure which, if any, of these attributes are transmitted along with the message.

The presence of message attributes, other than topic string, depends on whether the COMMINFO object states that they must be sent or not. If an attribute is not transmitted, the receiving application applies a default value. The default MQMD values are not necessarily the same as the MQMD_DEFAULT value, and are described later in this topic “Multicast message attributes” on page 175 .

The COMMINFO object contains the MCPROP attribute which controls how many of the MQMD fields and user properties flow with the message. By setting the value of this attribute to an appropriate level, you can control the size of the IBM MQ Multicast messages:

MCPROP
: The multicast properties control how many of the MQMD properties and user properties flow with the message.

  `ALL`
  : All user properties and all the fields of the MQMD are transmitted.

REPLY
Only user properties, and MQMD fields that deal with replying to the messages, are transmitted. These properties are:

- MsgType
- MessageId
- CorrelId
- ReplyToQ
- ReplyToQmgr

USER
Only the user properties are transmitted.

NONE
No user properties or MQMD fields are transmitted.

COMPAT
This value causes the transmission of the message to be done in a compatible mode to RMM, which allows some inter-operation with the current XMS applications and IBM Integration Bus RMM applications.

Multicast message attributes

Use this reference information to understand IBM MQ Multicast message attributes.

Message attributes can come from various places, such as the MQMD, the fields in the MQRFH2, and message properties.

The following table shows what happens when messages are sent subject to the value of MCPROP (described previously in this section), and the default value used when an attribute is not sent.

Table 5. Messaging attributes and how they relate to multicast

Attribute	Action when using multicast	Default if not transmitted
TopicString	Always Included	Not applicable
MQMQ StrucId	Not transmitted	Not applicable
MQMD Version	Not transmitted	Not applicable
Report	Included if not default	0
MsgType	Included if not default	MQMT_DATAGRAM
Expiry	Included if not default	0
Feedback	Included if not default	0
Encoding	Included if not default	MQENC_NORMAL(equiv)
CodedCharSetId	Included if not default	1208
Format	Included if not default	MQRFH2
Priority	Included if not default	4
Persistence	Included if not default	MQPER_NOT_PERSISTENT
MsgId	Included if not default	Null
CorrelId	Included if not default	Null
BackoutCount	Included if not default	0
ReplyToQ	Included if not default	Blank
ReplyToQMgr	Included if not default	Blank
UserIdentifier	Included if not default	Blank
AccountingToken	Included if not default	Null

Table 5. Messaging attributes and how they relate to multicast (continued)

Attribute	**Action when using multicast**	**Default if not transmitted**
PutApplType	Included if not default	MQAT_JAVA
PutApplName	Included if not default	Blank
PutDate	Included if not default	Blank
PutTime	Included if not default	Blank
ApplOriginData	Included if not default	Blank
GroupID	Excluded	Not applicable
MsgSeqNumber	Excluded	Not applicable
Offset	Excluded	Not applicable
MsgFlags	Excluded	Not applicable
OriginalLength	Excluded	Not applicable
UserProperties	Included	Not applicable

Enabling data conversion for Multicast messaging

Use this information to understand how data conversion works for IBM MQ Multicast messaging.

IBM MQ Multicast is a shared, connectionless protocol, and so it is not possible for each client to make specific requests for data conversion. Every client subscribed to the same multicast stream receives the same binary data; therefore, if IBM MQ data conversion is required, the conversion is performed locally at each client.

In a mixed platform installation, it might be that most of the clients require the data in a format that is not the native format of the transmitting application. In this situation the **CCSID** and **ENCODING** values of the multicast COMMINFO object can be used to define the encoding of the message transmission for efficiency.

IBM MQ Multicast supports data conversion of the message payload for the following built in formats:
- MQADMIN
- MQEVENT
- MQPCF
- MQRFH
- MQRFH2
- MQSTR

In addition to these formats, you can also define your own formats and use an MQDXP - Data-conversion exit parameter data conversion exit.

For information about programming data conversions, see Data conversion in the MQI for multicast messaging.

For more information about data conversion, see Data conversion.

For more information about data conversion exits and ClientExitPath, see ClientExitPath stanza of the client configuration file.

Multicast application monitoring

Use this information to learn about administering and monitoring IBM MQ Multicast.

The status of the current publishers and subscribers for multicast traffic (for example, the number of messages sent and received, or the number of messages lost) is periodically transmitted to the server from the client. When status is received, the COMMEV attribute of the COMMINFO object specifies whether or not the queue manager puts an event message on the SYSTEM.ADMIN.PUBSUB.EVENT. The event message contains the status information received. This information is an invaluable diagnostic aid in finding the source of a problem.

Use the MQSC command **DISPLAY CONN** to display connection information about the applications connected to the queue manager. For more information on the **DISPLAY CONN** command, see DISPLAY CONN.

Use the MQSC command **DISPLAY TPSTATUS** to display the status of your publishers and subscribers. For more information on the **DISPLAY TPSTATUS** command, see DISPLAY TPSTATUS.

COMMEV and the multicast message reliability indicator

The *reliability indicator*, used in conjunction with the **COMMEV** attribute of the COMMINFO object, is a key element in the monitoring of IBM MQ Multicast publishers and subscribers. The reliability indicator (the **MSGREL** field that is returned on the Publish or Subscribe status commands) is an IBM MQ indicator that illustrates the percentage of transmissions that have no errors Sometimes messages have to be retransmitted due to a transmission error, which is reflected in the value of **MSGREL**. Potential causes of transmission errors include slow subscribers, busy networks, and network outages. **COMMEV** controls whether event messages are generated for multicast handles that are created using the COMMINFO object and is set to one of three possible values:

DISABLED
Event messages are not written.

ENABLED
Event messages are always written, with a frequency defined in the COMMINFO **MONINT** parameter.

EXCEPTION
Event messages are written if the message reliability is below the reliability threshold. A message reliability level of 90% or less indicates that there might be a problem with the network configuration, or that one or more of the Publish/Subscribe applications is running too slowly:

- A value of **MSGREL(100,100)** indicates that there have been no issues in either the short term, or the long-term time frame.
- A value of **MSGREL(80,60)** indicates that 20% of the messages are currently having issues, but that it is also an improvement on the long-term value of 60.

Clients might continue transmitting and receiving multicast traffic even when the unicast connection to the queue manager is broken, therefore the data might be out of date.

Multicast message reliability

Use this information to learn how to set the IBM MQ Multicast subscription and message history.

A key element of overcoming transmission failure with multicast is the buffering of transmitted data (a history of messages to be kept at the transmitting end of the link) by IBM MQ. This process means that no buffering of messages is required in the putting application process because IBM MQ provides the reliability. The size of this history is configured via the communication information (COMMINFO) object, as described in the following information. A bigger transmission buffer means that there is more transmission history to be retransmitted if needed, but due to the nature of multicast, 100% assured delivery cannot be supported.

The IBM MQ Multicast message history is controlled in the communication information (COMMINFO) object by the **`MSGHIST`** attribute:

MSGHIST

This value is the amount of message history in kilobytes that is kept by the system to handle retransmissions in the case of NACKs (negative acknowledgments).

A value of `0` gives the least level of reliability. The default value is `100` KB.

The IBM MQ Multicast new subscription history is controlled in the communication information (COMMINFO) object by the **`NSUBHIST`** attribute:

NSUBHIST

The new subscriber history controls whether a subscriber joining a publication stream receives as much data as is currently available, or receives only publications made from the time of the subscription.

`NONE`

A value of `NONE` causes the transmitter to transmit only publication made from the time of the subscription. `NONE` is the default value.

`ALL`

A value of `ALL` causes the transmitter to retransmit as much history of the topic as is known. In some circumstances, this situation can give a similar behavior to retained publications.

Note: Using the value of `ALL` might have a detrimental effect on performance if there is a large topic history because all the topic history is retransmitted.

Advanced multicast tasks

Use this information to learn about advanced IBM MQ Multicast administration tasks such as configuring `.ini` files and interoperability with IBM MQ LLM.

For considerations for security in a Multicast installation, see Multicast security.

Bridging between multicast and non-multicast publish/subscribe domains

Use this information to understand what happens when a non-multicast publisher publishes to an IBM MQ Multicast enabled topic.

If a non-multicast publisher publishes to a topic that is defined as **MCAST** enabled and **BRIDGE** enabled, the queue manager transmits the message out over multicast directly to any subscribers that might be listening. A multicast publisher cannot publish to topics that are not multicast enabled.

Existing topics can be multicast enabled by setting the **MCAST** and **COMMINFO** parameters of a topic object. See Initial multicast concepts for more information about these parameters.

The COMMINFO object **BRIDGE** attribute controls publications from applications that are not using multicast. If **BRIDGE** is set to `ENABLED` and the **MCAST** parameter of the topic is also set to `ENABLED`, publications from applications that are not using multicast are bridged to applications that do. For more information on the **BRIDGE** parameter, see DEFINE COMMINFO.

Configuring the .ini files for Multicast

Use this information to understand the IBM MQ Multicast fields in the `.ini` files.

Additional IBM MQ Multicast configuration can be made in an `ini` file. The specific `ini` file that you must use is dependent on the type of applications:

- Client: Configure the *MQ_DATA_PATH* `/mqclient.ini` file.
- Queue manager: Configure the *MQ_DATA_PATH* `/qmgrs/`*QMNAME*`/qm.ini` file.

where *MQ_DATA_PATH* is the location of the IBM MQ data directory (`/var/mqm/mqclient.ini`), and *QMNAME* is the name of the queue manager to which the `.ini` file applies.

The `.ini` file contains fields used to fine-tune the behavior of IBM MQ Multicast:

```
Multicast:
Protocol        = IP | UDP
IPVersion       = IPv4 | IPv6 | ANY | BOTH
LimitTransRate    = DISABLED | STATIC | DYNAMIC
TransRateLimit    = 100000
SocketTTL       = 1
Batch         = NO
Loop        = 1
Interface       = <IPaddress>
FeedbackMode     = ACK | NACK | WAIT1
HeartbeatTimeout   = 20000
HeartbeatInterval   = 2000
```

Protocol

UDP In this mode, packets are sent using the UDP protocol. Network elements cannot provide assistance in the multicast distribution as they do in IP mode however. The packet format remains compatible with PGM. This is the default value.

IP In this mode, the transmitter sends raw IP packets. Network elements with PGM support assist in the reliable multicast packet distribution. This mode is fully compatible with the PGM standard.

IPVersion

IPv4 Communicate using the IPv4 protocol only. This is the default value.

IPv6 Communicate using the IPv6 protocol only.

ANY Communicate using IPv4, IPv6, or both, depending on which protocol is available.

BOTH Supports communication using both IPv4 and IPv6.

LimitTransRate

DISABLED
There is no transmission rate control. This is the default value.

STATIC
Implements static transmission rate control. The transmitter would not transmit at a rate exceeding the rate specified by the TransRateLimit parameter.

DYNAMIC
The transmitter adapts its transmission rate according to the feedback it gets from the receivers. In this case the transmission rate limit cannot be more than the value specified by the TransRateLimit parameter. The transmitter tries to reach an optimal transmission rate.

TransRateLimit
The transmission rate limit in Kbps.

SocketTTL
The value of SocketTTL determines if the multicast traffic can pass through a router, or the number of routers it can pass through.

Batch Controls whether messages are batched or sent immediately There are 2 possible values:

- *NO* The messages are not batched, they are sent immediately.
- *YES* The messages are batched.

Loop Set the value to 1 to enable multicast loop. Multicast loop defines whether the data sent is looped back to the host or not.

Interface
The IP address of the interface on which multicast traffic flows. For more information and troubleshooting, see: Testing multicast applications on a non-multicast network and Setting the appropriate network for multicast traffic

FeedbackMode

NACK
Feedback by negative acknowledgments. This is the default value.

ACK Feedback by positive acknowledgments.

WAIT1
Feedback by positive acknowledgments where the transmitter waits for only 1 ACK from any of the receivers.

HeartbeatTimeout
The heartbeat timeout in milliseconds. A value of 0 indicates that the heartbeat timeout events are not raised by the receiver or receivers of the topic. The default value is 20000.

HeartbeatInterval
The heartbeat interval in milliseconds. A value of 0 indicates that no heartbeats are sent. The heartbeat interval must be considerably smaller than the **`HeartbeatTimeout`** value to avoid false heartbeat timeout events. The default value is 2000.

Multicast interoperability with IBM MQ Low Latency Messaging

Use this information to understand the interoperability between IBM MQ Multicast and IBM MQ Low Latency Messaging (LLM).

Basic payload transfer is possible for an application using LLM, with another application using multicast to exchange messages in both directions. Although multicast uses LLM technology, the LLM product itself is not embedded. Therefore it is possible to install both LLM and IBM MQ Multicast, and operate and service the two products separately.

LLM applications that communicate with multicast might need to send and receive message properties. The IBM MQ message properties and MQMD fields are transmitted as LLM message properties with specific LLM message property codes as shown in the following table:

Table 6. IBM MQ message properties to IBM MQ LLM property mappings

IBM MQ property	IBM MQ LLM property type	LLM property kind	LLM property code
MQMD.Report	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1001
MQMD.MsgType	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1002
MQMD.Expiry	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1003
MQMD.Feedback	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1004
MQMD.Encoding	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1005
MQMD.CodedCharSetId	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1006
MQMD.Format	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_String	-1007
MQMD.Priority	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1008
MQMD.Persistence	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1009
MQMD.MsgId	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_ByteArray	-1010
MQMD.BackoutCount	RMM_MSG_PROP_INT32	LLM_PROP_KIND_Int32	-1012
MQMD.ReplyToQ	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_String	-1013
MQMD.ReplyToQMger	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_String	-1014
MQMD.PutDate	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_String	-1020
MQMD.PutTime	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_String	-1021
MQMD.ApplOriginData	RMM_MSG_PROP_BYTES	LLM_PROP_KIND_String	-1022
MQPubOptions	RMM_MSG_PROP_INT32	LLM_PROP_KIND_int32	-1053

For more information about LLM, see the LLM product documentation: IBM MQ Low Latency Messaging.

Administering HP Integrity NonStop Server

Use this information to learn about administration tasks for the IBM MQ client for HP Integrity NonStop Server.

Two administration tasks are available to you:

1. Manually starting the TMF/Gateway from Pathway.
2. Stopping the TMF/Gateway from Pathway.

Manually starting the TMF/Gateway from Pathway

You can allow Pathway to automatically start the TMF/Gateway on the first enlistment request, or you can manually start the TMF/Gateway from Pathway.

Procedure

To manually start the TMF/Gateway from Pathway, enter the following PATHCOM command:

```
START SERVER <server_class_name>
```

If a client application makes an enlistment request before the TMF/Gateway completes recovery of in-doubt transactions, the request is held for up to 1 second. If recovery does not complete within that time, the enlistment is rejected. The client then receives an MQRC_UOW_ENLISTMENT_ERROR error from use of a transactional MQI.

Stopping the TMF/Gateway from Pathway

This task describes how to stop the TMF/Gateway from Pathway, and how to restart the TMF/Gateway after you stop it.

Procedure

1. To prevent any new enlistment requests being made to the TMF/Gateway, enter the following command:
   ```
   FREEZE SERVER <server_class_name>
   ```
2. To trigger the TMF/Gateway to complete any in-flight operations and to end, enter the following command:
   ```
   STOP SERVER <server_class_name>
   ```
3. To allow the TMF/Gateway to restart either automatically on first enlistment or manually, following steps 1 and 2, enter the following command:
   ```
   THAW SERVER <server_class_name>
   ```
   Applications are prevented from making new enlistment requests and it is not possible to issue the **START** command until you issue the **THAW** command.

Administering IBM i

IBM i

Introduces the methods available to you to administer IBM MQ on IBM i.

Administration tasks include creating, starting, altering, viewing, stopping, and deleting clusters, processes, and IBM MQ objects (queue managers, queues, namelists, process definitions, channels, client connection channels, listeners, services, and authentication information objects).

See the following links for details of how to administer IBM MQ for IBM i:
- "Managing IBM MQ for IBM i using CL commands"
- "Alternative ways of administering IBM MQ for IBM i" on page 197
- "Work management" on page 202

Related concepts:

"Availability, backup, recovery, and restart" on page 209
Use this information to understand how IBM MQ for IBM i uses the IBM i journaling support to help its backup and restore strategy.

Related reference:

"Quiescing IBM MQ for IBM i" on page 252
This section explains how to quiesce (end gracefully) IBM MQ for IBM i

Related information:

Changing configuration information on IBM i

Managing IBM MQ for IBM i using CL commands

Use this information to understand the IBM MQ IBM i commands.

Most groups of IBM MQ commands, including those associated with queue managers, queues, topics, channels, namelists, process definitions, and authentication information objects can be accessed using the relevant `WRK*` command.

The principal command in the set is `WRKMQM`. This command allows you, for example, to display a list of all the queue managers on the system, together with status information. Alternatively, you can process all queue-manager specific commands using various options against each entry.

From the `WRKMQM` command you can select specific areas of each queue manager, for example, working with channels, topics or queues, and from there select individual objects.

Recording IBM MQ application definitions

When you create or customize IBM MQ applications, it is useful to keep a record of all IBM MQ definitions created. This record can be used for:
- Recovery purposes
- Maintenance

- Rolling out IBM MQ applications

You can record IBM MQ application definitions in 1 of 2 ways:

1. Creating CL programs to generate your IBM MQ definitions for the server.
2. Creating MQSC text files as SRC members to generate your IBM MQ definitions using the cross-platform IBM MQ command language.

For further details about defining queue objects, see “Script (MQSC) Commands” on page 74 and “Using Programmable Command Formats” on page 7.

Before you start using the IBM MQ for IBM i using CL commands

Use this information to start the IBM MQ subsystem and create a local queue manager.

Before you begin

Ensure that the IBM MQ subsystem is running (using the command `STRSBS QMQM/QMQM`), and that the job queue associated with that subsystem is not held. By default, the IBM MQ subsystem and job queue are both named QMQM in library QMQM.

About this task

Using the IBM i command line to start a queue manager

Procedure

1. Create a local queue manager by issuing the **CRTMQM** command from an IBM i command line. When you create a queue manager, you have the option of making that queue manager the default queue manager. The default queue manager (of which there can only be one) is the queue manager to which a CL command applies, if the queue manager name parameter (MQMNAME) is omitted.
2. Start a local queue manager by issuing the **STRMQM** command from an IBM i command line. If the queue manager startup takes more than a few seconds IBM MQ will show status messages intermittently detailing the start up progress. For more information on these messages see Reason codes.

What to do next

You can stop a queue manager by issuing the **ENDMQM** command from the IBM i command line, and control a queue manager by issuing other IBM MQ commands from an IBM i command line.

Remote queue managers cannot be started remotely but must be created and started in their systems by local operators. An exception to this is where remote operating facilities (outside IBM MQ for IBM i) exist to enable such operations.

The local queue administrator cannot stop a remote queue manager.

Note: As part of quiescing an IBM MQ system, you have to quiesce the active queue managers. This is described in “Quiescing IBM MQ for IBM i” on page 252.

Creating IBM MQ for IBM i objects

Use this information to understand the methods for creating IBM MQ objects for IBM i.

Before you begin

The following tasks suggest various ways in which you can use IBM MQ for IBM i from the command line.

About this task

There are two online methods to create IBM MQ objects, which are:

Procedure

1. Using a Create command, for example: The **`Create MQM Queue`** command: **`CRTMQMQ`**
2. Using a Work with MQM object command, followed by F6, for example: The **`Work with MQM Queues`** command: **`WRKMQMQ`**

What to do next

For a list of all commands see IBM MQ for IBM i CL commands.

Note: All MQM commands can be submitted from the Message Queue Manager Commands menu. To display this menu, type `GO CMDMQM` on the command line and press the `Enter` key.

The system displays the prompt panel automatically when you select a command from this menu. To display the prompt panel for a command that you have typed directly on the command line, press `F4` before pressing the `Enter` key.

Creating a local queue using the CRTMQMQ command:
Procedure

1. Type `CHGMQM` on the command line and press the `F4` key.
2. On the Create MQM Queue panel, type the name of the queue that you want to create in the `Queue name` field. To specify a mixed case name, you enclose the name in apostrophes.
3. Type `*LCL` in the `Queue type` field.
4. Specify a queue manager name, unless you are using the default queue manager, and press the `Enter` key. You can overtype any of the values with a new value. Scroll forward to see further fields. The options used for clusters are at the end of the list of options.
5. When you have changed any values, press the `Enter` key to create the queue.

Creating a local queue using the WRKMQMQ command:
Procedure

1. Type `WRKMQMQ` on the command line.
2. Enter the name of a queue manager.
3. If you want to display the prompt panel, press `F4`. The prompt panel is useful to reduce the number of queues displayed, by specifying a generic queue name or queue type.
4. Press `Enter` and the Work with MQM Queues panel is displayed. You can overtype any of the values with a new value. Scroll forward to see further fields. The options used for clusters are at the end of the list of options.
5. Press `F6` to create a new queue; this takes you to the CRTMQMQ panel. See "Creating a local queue using the CRTMQMQ command" for instructions on how to create the queue. When you have created the queue, the Work with MQM Queues panel is displayed again. The new queue is added to the list when you press `F5=Refresh`.

Altering queue manager attributes:
About this task

To alter the attributes of the queue manager specified on the **CHGMQM** command, specifying the attributes and values that you want to change. For example, use the following options to alter the attributes of `jupiter.queue.manager`:

Procedure

Type **CHGMQM** on the command line and press the `F4` key.

Results

The command changes the dead-letter queue used, and enables inhibit events.

Working with local queues

This section contains examples of some of the commands that you can use to manage local queues. All the commands shown are also available using options from the WRKMQMQ command panel.

Defining a local queue

For an application, the local queue manager is the queue manager to which the application is connected. Queues that are managed by the local queue manager are said to be local to that queue manager.

Use the command **CRTMQMQ QTYPE *LCL** to create a definition of a local queue and also to create the data structure that is called a queue. You can also modify the queue characteristics from those of the default local queue.

In this example, the queue we define, `orange.local.queue`, is specified to have these characteristics:

- It is enabled for gets, disabled for puts, and operates on a first-in-first-out (FIFO) basis.
- It is an *ordinary* queue, that is, it is not an initiation queue or a transmission queue, and it does not generate trigger messages.
- The maximum queue depth is 1000 messages; the maximum message length is 2000 bytes.

The following command does this on the default queue manager:

```
CRTMQMQ QNAME('orange.local.queue') QTYPE(*LCL)
TEXT('Queue for messages from other systems')
PUTENBL(*NO)
GETENBL(*YES)
TRGENBL(*NO)
MSGDLYSEQ(*FIFO)
MAXDEPTH(1000)
MAXMSGLEN(2000)
USAGE(*NORMAL)
```

Note:

1. `USAGE *NORMAL` indicates that this queue is not a transmission queue.
2. If you already have a local queue with the name `orange.local.queue` on the same queue manager, then this command fails. Use the `REPLACE *YES` attribute if you want to overwrite the existing definition of a queue, but see also "Changing local queue attributes" on page 187.

Defining a dead-letter queue

Each queue manager must have a local queue to be used as a dead-letter queue so that messages that cannot be delivered to their correct destination can be stored for later retrieval. You must explicitly tell the queue manager about the dead-letter queue. You can do this by specifying a dead-letter queue on the **CRTMQM** command, or you can use the **CHGMQM** command to specify one later. You must also define the dead-letter queue before it can be used.

A sample dead-letter queue called `SYSTEM.DEAD.LETTER.QUEUE` is supplied with the product. This queue is automatically created when you create the queue manager. You can modify this definition if required. There is no need to rename it, although you can if you like.

A dead-letter queue has no special requirements except that:
- It must be a local queue.
- Its MAXMSGL (maximum message length) attribute must enable the queue to accommodate the largest messages that the queue manager has to handle **plus** the size of the dead-letter header (MQDLH).

IBM MQ provides a dead-letter queue handler that allows you to specify how messages found on a dead-letter queue are to be processed or removed. For further information, see The IBM MQ for IBM i dead-letter queue handler.

Displaying default object attributes

When you define an IBM MQ object, it takes any attributes that you do not specify from the default object. For example, when you define a local queue, the queue inherits any attributes that you omit in the definition from the default local queue, which is called `SYSTEM.DEFAULT.LOCAL.QUEUE`. To see exactly what these attributes are, use the following command:

```
DSPMQMQ QNAME(SYSTEM.DEFAULT.LOCAL.QUEUE) MQMNAME(MYQUEUEMANAGER)
```

Copying a local queue definition

You can copy a queue definition using the **CPYMQMQ** command. For example:

```
CPYMQMQ FROMQ('orange.local.queue') TOQ('magenta.queue') MQMNAME(MYQUEUEMANAGER)
```

This command creates a queue with the same attributes as our original queue `orange.local.queue`, rather than those of the system default local queue.

You can also use the **CPYMQMQ** command to copy a queue definition, but substituting one or more changes to the attributes of the original. For example:

```
CPYMQMQ FROMQ('orange.local.queue') TOQ('third.queue') MQMNAME(MYQUEUEMANAGER)
MAXMSGLEN(1024)
```

This command copies the attributes of the queue `orange.local.queue` to the queue `third.queue`, but specifies that the maximum message length on the new queue is to be 1024 bytes, rather than 2000.

Note: When you use the **CPYMQMQ** command, you copy the queue attributes only, not the messages on the queue.

Changing local queue attributes

You can change queue attributes in two ways, using either the **CHGMQMQ** command or the **CPYMQMQ** command with the REPLACE *YES attribute. In "Defining a local queue" on page 186, you defined the queue `orange.local.queue`. If, for example, you need to increase the maximum message length on this queue to 10,000 bytes.
- Using the **CHGMQMQ** command:

  ```
  CHGMQMQ QNAME('orange.local.queue') MQMNAME(MYQUEUEMANAGER) MAXMSGLEN(10000)
  ```

  This command changes a single attribute, that of the maximum message length; all the other attributes remain the same.

- Using the **CRTMQMQ** command with the REPLACE *YES option, for example:

  ```
  CRTMQMQ QNAME('orange.local.queue') QTYPE(*LCL) MQMNAME(MYQUEUEMANAGER)
  MAXMSGLEN(10000) REPLACE(*YES)
  ```

  This command changes not only the maximum message length, but all the other attributes, which are given their default values. The queue is now put enabled whereas previously it was put inhibited. Put enabled is the default, as specified by the queue `SYSTEM.DEFAULT.LOCAL.QUEUE`, unless you have changed it.

  If you ***decrease*** the maximum message length on an existing queue, existing messages are not affected. Any new messages, however, must meet the new criteria.

Clearing a local queue

To delete all the messages from a local queue called `magenta.queue`, use the following command:

```
CLRMQMQ QNAME('magenta.queue') MQMNAME(MYQUEUEMANAGER)
```

You cannot clear a queue if:
- There are uncommitted messages that have been put on the queue under syncpoint.
- An application currently has the queue open.

Deleting a local queue

Use the command **DLTMQMQ** to delete a local queue.

A queue cannot be deleted if it has uncommitted messages on it, or if it is in use.

Enabling large queues

IBM MQ supports queues larger than 2 GB. See your operating system documentation for information on how to enable IBM i to support large files.

The IBM i product documentation can be found here: http://publib.boulder.ibm.com/iseries/

Some utilities might not be able to cope with files greater than 2 GB. Before enabling large file support, check your operating system documentation for information on restrictions on such support.

Working with alias queues

This section contains examples of some of the commands that you can use to manage alias queues. All the commands shown are also available using options from the WRKMQMQ command panel.

An alias queue (sometimes known as a queue alias) provides a method of redirecting MQI calls. An alias queue is not a real queue but a definition that resolves to a real queue. The alias queue definition contains a target queue name, which is specified by the TGTQNAME attribute.

When an application specifies an alias queue in an MQI call, the queue manager resolves the real queue name at run time.

For example, an application has been developed to put messages on a queue called `my.alias.queue`. It specifies the name of this queue when it makes an **MQOPEN** request and, indirectly, if it puts a message on this queue. The application is not aware that the queue is an alias queue. For each MQI call using this alias, the queue manager resolves the real queue name, which could be either a local queue or a remote queue defined at this queue manager.

By changing the value of the TGTQNAME attribute, you can redirect MQI calls to another queue, possibly on another queue manager. This is useful for maintenance, migration, and load-balancing.

Defining an alias queue

The following command creates an alias queue:

```
CRTMQMQ QNAME('my.alias.queue') QTYPE(*ALS) TGTQNAME('yellow.queue')
MQMNAME(MYQUEUEMANAGER)
```

This command redirects MQI calls that specify `my.alias.queue` to the queue `yellow.queue`. The command does not create the target queue; the MQI calls fail if the queue `yellow.queue` does not exist at run time.

If you change the alias definition, you can redirect the MQI calls to another queue. For example:

```
CHGMQMQ QNAME('my.alias.queue') TGTQNAME('magenta.queue') MQMNAME(MYQUEUEMANAGER)
```

This command redirects MQI calls to another queue, `magenta.queue`.

You can also use alias queues to make a single queue (the target queue) appear to have different attributes for different applications. You do this by defining two aliases, one for each application. Suppose there are two applications:

- Application ALPHA can put messages on `yellow.queue`, but is not allowed to get messages from it.
- Application BETA can get messages from `yellow.queue`, but is not allowed to put messages on it.

You can do this using the following commands:

```
/* This alias is put enabled and get disabled for application ALPHA */

CRTMQMQ QNAME('alphas.alias.queue') QTYPE(*ALS)  TGTQNAME('yellow.queue')
PUTENBL(*YES) GETENBL(*NO) MQMNAME(MYQUEUEMANAGER)

/* This alias is put disabled and get enabled for application BETA */

CRTMQMQ QNAME('betas.alias.queue') QTYPE(*ALS) TGTQNAME('yellow.queue')
PUTENBL(*NO) GETENBL(*YES) MQMNAME(MYQUEUEMANAGER)
```

ALPHA uses the queue name `alphas.alias.queue` in its MQI calls; BETA uses the queue name `betas.alias.queue`. They both access the same queue, but in different ways.

You can use the REPLACE *YES attribute when you define alias queues, in the same way that you use these attributes with local queues.

Using other commands with alias queues

You can use the appropriate commands to display or change alias queue attributes. For example:

```
* Display the alias queue's attributes */

DSPMQMQ QNAME('alphas.alias.queue') MQMNAME(MYQUEUEMANAGER)

/* ALTER the base queue name, to which the alias resolves. */
/* FORCE = Force the change even if the queue is open. */

CHQMQMQ QNAME('alphas.alias.queue') TGTQNAME('orange.local.queue') FORCE(*YES)
MQMNAME(MYQUEUEMANAGER)
```

Working with model queues

This section contains examples of some of the commands that you can use to manage model queues. All the commands shown are also available using options from the WRKMQMQ command panel.

A queue manager creates a dynamic queue if it receives an MQI call from an application specifying a queue name that has been defined as a model queue. The name of the new dynamic queue is generated by the queue manager when the queue is created. A model queue is a template that specifies the attributes of any dynamic queues created from it.

Model queues provide a convenient method for applications to create queues as they are required.

Defining a model queue

You define a model queue with a set of attributes in the same way that you define a local queue. Model queues and local queues have the same set of attributes, except that on model queues you can specify whether the dynamic queues created are temporary or permanent. (Permanent queues are maintained across queue manager restarts, temporary ones are not). For example:

```
CRTMQMQ QNAME('green.model.queue') QTYPE(*MDL) DFNTYPE(*PERMDYN)
```

This command creates a model queue definition. From the DFNTYPE attribute, the actual queues created from this template are permanent dynamic queues. The attributes not specified are automatically copied from the `SYSYTEM.DEFAULT.MODEL.QUEUE` default queue.

You can use the REPLACE *YES attribute when you define model queues, in the same way that you use them with local queues.

Using other commands with model queues

You can use the appropriate commands to display or alter a model queue's attributes. For example:

```
/* Display the model queue's attributes */

DSPMQMQ MQMNAME(MYQUEUEMANAGER) QNAME('green.model.queue')

/* ALTER the model queue to enable puts on any */
/* dynamic queue created from this model. */

CHGMQMQ MQMNAME(MYQUEUEMANAGER) QNAME('blue.model.queue') PUTENBL(*YES)
```

Working with triggering

Use this information to learn about triggering and process definitions.

IBM MQ provides a facility for starting an application automatically when certain conditions on a queue are met. One example of the conditions is when the number of messages on a queue reaches a specified number. This facility is called *triggering* and is described in detail in Triggering channels.

What is triggering?

The queue manager defines certain conditions as constituting trigger events. If triggering is enabled for a queue and a trigger event occurs, the queue manager sends a trigger message to a queue called an initiation queue. The presence of the trigger message on the initiation queue indicates that a trigger event has occurred.

Trigger messages generated by the queue manager are not persistent. This has the effect of reducing logging (thereby improving performance), and minimizing duplicates during restart, so improving restart time.

What is the trigger monitor?

The program which processes the initiation queue is called a trigger-monitor application, and its function is to read the trigger message and take appropriate action, based on the information contained in the trigger message. Normally this action would be to start some other application to process the queue which caused the trigger message to be generated. From the point of view of the queue manager, there is nothing special about the trigger-monitor application - it is another application that reads messages from a queue (the initiation queue).

Altering the job submission attributes of the trigger monitor

The trigger monitor supplied as command **STRMQMTRM** submits a job for each trigger message using the system default job description, QDFTJOBD. This has limitations in that the submitted jobs are always called QDFTJOBD and have the attributes of the default job description including the library list, *SYSVAL. IBM MQ provides a method for overriding these attributes. For example, it is possible to customize the submitted jobs to have more meaningful job names as follows:

1. In the job description specify the description you want, for example logging values.
2. Specify the Environment Data of the process definition used in the triggering process:
   ```
   CHGMQMPRC PRCNAME(MY_PROCESS) MQMNAME(MHA3) ENVDATA ('JOBD(MYLIB/TRIGJOBD)')
   ```

   The Trigger Monitor performs a SBMJOB using the specified description.

It is possible to override other attributes of the SBMJOB by specifying the appropriate keyword and value in the Environment Data of the process definition. The only exception to this is the CMD keyword because this attribute is filled by the trigger monitor. An example of the command to specify the Environment Data of the process definition where both the job name and description are to be altered follows:

```
CHGMQMPRC PRCNAME(MY_PROCESS) MQMNAME(MHA3) ENVDATA ('JOBD(MYLIB/TRIGJOB)
JOB(TRIGGER)')
```

Defining an application queue for triggering

An application queue is a local queue that is used by applications for messaging, through the MQI. Triggering requires a number of queue attributes to be defined on the application queue. Triggering itself is enabled by the TRGENBL attribute.

In this example, a trigger event is to be generated when there are 100 messages of priority 5 or higher on the local queue motor.insurance.queue, as follows:

```
CRTMQMQ MQMNAME(MYQUEUEMANAGER) QNAME('motor.insurance.queue') QTYPE(*LCL)
PRCNAME('motor.insurance.quote.process') MAXMSGLEN(2000)
DFTMSGPST(*YES) INITQNAME('motor.ins.init.queue')
TRGENBL(*YES) TRGTYPE(*DEPTH) TRGDEPTH(100) TRGMSGPTY(5)
```

where the parameters are:

MQMNAME(MYQUEUEMANAGER)
: The name of the queue manager.

QNAME('motor.insurance.queue')
: The name of the application queue being defined.

PRCNAME('motor.insurance.quote.process')
: The name of the application to be started by a trigger monitor program.

MAXMSGLEN(2000)
: The maximum length of messages on the queue.

DFTMSGPST(*YES)
: Messages on this queue are persistent by default.

INITQNAME('motor.ins.init.queue')
: The name of the initiation queue on which the queue manager is to put the trigger message.

TRGENBL(*YES)
: The trigger attribute value.

TRGTYPE(*DEPTH)
: A trigger event is generated when the number of messages of the required priority (**TRGMSGPTY**) reaches the number specified in **TRGDEPTH**.

TRGDEPTH(100)
: The number of messages required to generate a trigger event.

TRGMSGPTY(5)
: The priority of messages that are to be counted by the queue manager in deciding whether to generate a trigger event. Only messages with priority 5 or higher are counted.

Defining an initiation queue

When a trigger event occurs, the queue manager puts a trigger message on the initiation queue specified in the application queue definition. Initiation queues have no special settings, but you can use the following definition of the local queue `motor.ins.init.queue` for guidance:

```
CRTMQMQ MQMNAME(MYQUEUEMANAGER) QNAME('motor.ins.init.queue') QTYPE(*LCL)
GETENBL(*YES) SHARE(*NO) TRGTYPE(*NONE)
MAXMSGL(2000)
MAXDEPTH(1000)
```

Creating a process definition

Use the **CRTMQMPRC** command to create a process definition. A process definition associates an application queue with the application that is to process messages from the queue. This is done through the PRCNAME attribute on the application queue `motor.insurance.queue`. The following command creates the required process, `motor.insurance.quote.process`, identified in this example:

```
CRTMQMPRC MQMNAME(MYQUEUEMANAGER) PRCNAME('motor.insurance.quote.process')
TEXT('Insurance request message processing')
APPTYPE(*OS400) APPID(MQTEST/TESTPROG)
USRDATA('open, close, 235')
```

where the parameters are:

MQMNAME(MYQUEUEMANAGER)
: The name of the queue manager.

PRCNAME('motor.insurance.quote.process')
: The name of the process definition.

TEXT('Insurance request message processing')
: A description of the application program to which this definition relates. This text is displayed when you use the **DSPMQMPRC** command. This can help you to identify what the process does. If you use spaces in the string, you must enclose the string in single quotation marks.

APPTYPE(*OS400)
: The type of application to be started.

APPID(MQTEST/TESTPROG)
: The name of the application executable file, specified as a fully qualified file name.

USRDATA('open, close, 235')
: User-defined data, which can be used by the application.

Displaying your process definition

Use the **DSPMQMPRC** command to examine the results of your definition. For example:

```
MQMNAME(MYQUEUEMANAGER) DSPMQMPRC('motor.insurance.quote.process')
```

You can also use the **CHGMQMPRC** command to alter an existing process definition, and the **DLTMQMPRC** command to delete a process definition.

Displaying your process definition

Use the **DSPMQMPRC** command to examine the results of your definition. For example:

```
MQMNAME(MYQUEUEMANAGER) DSPMQMPRC('motor.insurance.quote.process')
```

You can also use the **CHGMQMPRC** command to alter an existing process definition, and the **DLTMQMPRC** command to delete a process definition.

Communicating between two systems

The following example illustrates how to set up two IBM MQ for IBM i systems, using CL commands, so that they can communicate with one another.

The systems are called SYSTEMA and SYSTEMB, and the communications protocol used is TCP/IP.

Carry out the following procedure:

1. Create a queue manager on SYSTEMA, calling it QMGRA1.
   ```
   CRTMQM   MQMNAME(QMGRA1) TEXT('System A - Queue +
   Manager 1') UDLMSGQ(SYSTEM.DEAD.LETTER.QUEUE)
   ```
2. Start this queue manager.
   ```
   STRMQM   MQMNAME(QMGRA1)
   ```
3. Define the IBM MQ objects on SYSTEMA that you need to send messages to a queue manager on SYSTEMB.
   ```
   /* Transmission queue */
   CRTMQMQ  QNAME(XMITQ.TO.QMGRB1) QTYPE(*LCL) +
   MQMNAME(QMGRA1) TEXT('Transmission Queue +
   to QMGRB1') MAXDEPTH(5000) USAGE(*TMQ)

   /* Remote queue that points to a queue called TARGETB        */
   /* TARGETB belongs to queue manager QMGRB1 on SYSTEMB        */
   CRTMQMQ  QNAME(TARGETB.ON.QMGRB1) QTYPE(*RMT) +
   MQMNAME(QMGRA1) TEXT('Remote Q pointing +
   at Q TARGETB on QMGRB1 on Remote System +
   SYSTEMB') RMTQNAME(TARGETB) +
   RMTMQMNAME(QMGRB1) TMQNAME(XMITQ.TO.QMGRB1)

   /* TCP/IP sender channel to send messages to the queue manager on SYSTEMB*/
   CRTMQMCHL CHLNAME(QMGRA1.TO.QMGRB1) CHLTYPE(*SDR) +
   MQMNAME(QMGRA1) TRPTYPE(*TCP) +
   TEXT('Sender Channel From QMGRA1 on +
   SYSTEMA to QMGRB1 on SYSTEMB') +
   CONNAME(SYSTEMB) TMQNAME(XMITQ.TO.QMGRB1)
   ```
4. Create a queue manager on SYSTEMB, calling it QMGRB1.
   ```
   CRTMQM   MQMNAME(QMGRB1) TEXT('System B - Queue +
   Manager 1') UDLMSGQ(SYSTEM.DEAD.LETTER.QUEUE)
   ```
5. Start the queue manager on SYSTEMB.
   ```
   STRMQM   MQMNAME(QMGRB1)
   ```
6. Define the IBM MQ objects that you need to receive messages from the queue manager on SYSTEMA.

```
/* Local queue to receive messages on */
CRTMQMQ  QNAME(TARGETB) QTYPE(*LCL) MQMNAME(QMGRB1) +
TEXT('Sample Local Queue for QMGRB1')

/* Receiver channel of the same name as the sender channel on SYSTEMA */
CRTMQMCHL CHLNAME(QMGRA1.TO.QMGRB1) CHLTYPE(*RCVR) +
MQMNAME(QMGRB1) TRPTYPE(*TCP) +
TEXT('Receiver Channel from QMGRA1 to +
QMGRB1')
```

7. Finally, start a TCP/IP listener on SYSTEMB so that the channel can be started. This example uses the default port of 1414.

   ```
   STRMQMLSR MQMNAME(QMGRB1)
   ```

You are now ready to send test messages between SYSTEMA and SYSTEMB. Using one of the supplied samples, put a series of messages to your remote queue on SYSTEMA.

Start the channel on SYSTEMA, either by using the command **STRMQMCHL** , or by using the command **WRKMQMCHL** and entering a start request (Option 14) against the sender channel.

The channel should go to RUNNING status and the messages are sent to queue TARGETB on SYSTEMB.

Check your messages by issuing the command:

```
WRKMQMMSG QNAME(TARGETB) MQMNAME(QMGRB1).
```

Sample resource definitions

This sample contains the AMQSAMP4 sample IBM i CL program.

```
/********************************************************************/
/*                              */
/* Program name: AMQSAMP4                     */
/*                              */
/* Description: Sample CL program defining MQM queues        */
/*      to use with the sample programs          */
/*      Can be run, with changes as needed, after      */

Alternative ways of administering IBM MQ for IBM i

Use this information to learn about IBM MQ for IBM i, MQSC commands, PCF commands, and remote administration.

You can use IBM MQ instrumentation events to monitor the operation of queue managers. See Instrumentation events for information about IBM MQ instrumentation events and how to use them.

You normally use IBM i CL commands to administer IBM MQ for IBM i. See “Managing IBM MQ for IBM i using CL commands” on page 183 for an overview of these commands.

Using CL commands is the preferred method of administering the system. However, you can use various other methods. This section gives an overview of those methods and includes the following topics:

Local and remote administration

You administer IBM MQ for IBM i objects locally or remotely.

Local administration means carrying out administration tasks on any queue managers that you have defined on your local system. In IBM MQ, you can consider this as local administration because no IBM MQ channels are involved, that is, the communication is managed by the operating system. To perform this type of task, you must either log onto the remote system and issue the commands from there, or create a process that can issue the commands for you.

IBM MQ supports administration from a single point through what is known as *remote administration*. Remote administration consists of sending programmable command format (PCF) control messages to the `SYSTEM.ADMIN.COMMAND.QUEUE` on the target queue manager.

There are a number of ways of generating PCF messages. These are:

1. Writing a program using PCF messages. See "Administration using PCF commands" on page 199.
2. Writing a program using the MQAI, which sends out PCF messages. See "Using the MQAI to simplify the use of PCFs" on page 18.
3. Using the IBM MQ Explorer, available with IBM MQ for Windows, which allows you to use a graphical user interface (GUI) and generates the correct PCF messages. See "Using the IBM MQ Explorer with IBM MQ for IBM i" on page 200.
4. Use **`STRMQMMQSC`** to send commands indirectly to a remote queue manager. See "Administration using MQSC commands."

For example, you can issue a remote command to change a queue definition on a remote queue manager.

Some commands cannot be issued in this way, in particular, creating or starting queue managers and starting command servers. To perform this type of task, you must either log onto the remote system and issue the commands from there or create a process that can issue the commands for you.

Administration using MQSC commands

Use this information to learn about MQSC commands, and how to use them to administer IBM MQ for IBM i.

IBM MQ script (MQSC) commands are written in human-readable form, that is, in EBCDIC text. You use MQSC commands to manage queue manager objects, including the queue manager itself, queues, process definitions, namelists, channels, client connection channels, listeners, services, topics, and authentication information objects.

You issue MQSC commands to a queue manager using the **`STRMQMMQSC`** IBM MQ CL command. This method is a batch method only, taking its input from a source physical file in the server library system. The default name for this source physical file is `QMQSC`.

Attention: Do not use the QTEMP library as the source library to STRMQMMQSC, as the usage of the QTEMP library is limited. You must use another library as an input file to the command.

IBM MQ for IBM i does not supply a source file called `QMQSC`. To process MQSC commands you must create the `QMQSC` source file in a library of your choice, by issuing the following command:

```
CRTSRCPF FILE(MYLIB/QMQSC) RCDLEN(240) TEXT('IBM MQ - MQSC Source')
```

MQSC source is held in members within this source file. To work with the members enter the following command:

```
WRKMBRPDM MYLIB/QMQSC
```

You can now add new members and maintain existing ones

You can also enter MQSC commands interactively, by issuing RUNMQSC or:

1. Typing in the queue manager name and pressing the `Enter` key to access the **`WRKMQM`** results panel.
2. Selecting `F23=More options` on this panel.
3. Selecting option 26 against an active queue manager on the panel shown in Figure 30.

To end such an MQSC session, type **end** .

Figure 30 is an extract from an MQSC command file showing an MQSC command (DEFINE QLOCAL) with its attributes.

```
.
.
DEFINE QLOCAL(ORANGE.LOCAL.QUEUE) REPLACE +
DESCR(' ') +
PUT(ENABLED) +
DEFPRTY(0) +
DEFPSIST(NO) +
GET(ENABLED) +
MAXDEPTH(5000) +
MAXMSGL(1024) +
DEFSOPT(SHARED) +
NOHARDENBO +
USAGE(NORMAL) +
NOTRIGGER;
.
.
```

Figure 30. Extract from the MQSC command file, myprog.in

For portability among IBM MQ environments, limit the line length in MQSC command files to 72 characters. The plus sign indicates that the command is continued on the next line.

Object attributes specified in MQSC are shown in this section in uppercase (for example, RQMNAME), although they are not case-sensitive.

Note:

1. The format of an MQSC file does not depend on its location in the file system.
2. MQSC attribute names are limited to eight characters.
3. MQSC commands are available on other platforms, including z/OS.

For a description of each MQSC command and its syntax, see “Script (MQSC) Commands” on page 74.

Administration using PCF commands

The purpose of IBM MQ programmable command format (PCF) commands is to allow administration tasks to be programmed into an administration program. In this way you can create queues and process definitions, and change queue managers, from a program.

PCF commands cover the same range of functions provided by MQSC commands. However, unlike MQSC commands, PCF commands and their replies are not in a text format that you can read.

You can write a program to issue PCF commands to any queue manager in the network from a single node. In this way, you can both centralize and automate administration tasks.

Each PCF command is a data structure that is embedded in the application data part of an IBM MQ message. Each command is sent to the target queue manager using the MQI function MQPUT in the same way as any other message. The command server on the queue manager receiving the message interprets it as a command message and runs the command. To get the replies, the application issues an MQGET call and the reply data is returned in another data structure. The application can then process the reply and act accordingly.

Briefly, these are some of the things the application programmer must specify to create a PCF command message:

Message descriptor

This is a standard IBM MQ message descriptor, in which:

- Message type (*MsgType*) is MQMT_REQUEST.
- Message format (*Format*) is MQFMT_ADMIN.

Application data

Contains the PCF message including the PCF header, in which:

- The PCF message type (*Type*) specifies MQCFT_COMMAND.
- The command identifier specifies the command, for example, *Change Queue* (MQCMD_CHANGE_Q).

Escape PCFs are PCF commands that contain MQSC commands within the message text. You can use PCFs to send commands to a remote queue manager. See "Using the MQAI to simplify the use of PCFs" on page 18 for further information.

For a complete description of the PCF data structures and how to implement them, see Structures for commands and responses.

Using the IBM MQ Explorer with IBM MQ for IBM i

Use this information to administer IBM MQ for IBM i using the IBM MQ Explorer.

IBM MQ for Windows (x86 platform), and IBM MQ for Linux (x86 and x86-64 platforms) provide an administration interface called the IBM MQ Explorer to perform administration tasks as an alternative to using CL, control, or MQSC commands.

The IBM MQ Explorer allows you to perform local or remote administration of your network from a computer running Windows (x86 platform), or Linux (x86 and x86-64 platforms), by pointing the IBM MQ Explorer at the queue managers and clusters you are interested in. The platforms and levels of IBM MQ that can be administered using the IBM MQ Explorer are described in Remote queue managers.

With the IBM MQ Explorer, you can:

- Start and stop a queue manager (on your local machine only).
- Define, display, and alter the definitions of IBM MQ objects such as queues, topics, and channels.
- Browse the messages on a queue.
- Start and stop a channel.
- View status information about a channel.
- View queue managers in a cluster.
- Check to see which applications, users, or channels have a particular queue open.
- Create a new queue manager cluster using the Create New Cluster wizard.
- Add a queue manager to a cluster using the Add Queue Manager to Cluster wizard.
- Manage the authentication information object, used with Secure Sockets Layer (SSL) channel security.

Using the online guidance, you can:

- Define and control various resources including queue managers, queues, channels, process definitions, client connection channels, listeners, topics, services, namelists, and clusters.
- Start or stop a queue manager and its associated processes.

- View queue managers and their associated objects on your workstation or from other workstations.
- Check the status of queue managers, clusters, and channels.

Ensure that you have satisfied the following requirements before attempting to use the IBM MQ Explorer to manage IBM MQ on a server machine. Check that:

1. A command server is running for **any** queue manager being administered, started on the server by the CL command **`STRMQMCSVR`**.
2. A suitable TCP/IP listener exists for every remote queue manager. This is the IBM MQ listener started by the **`STRMQMLSR`** command.
3. The server connection channel, called `SYSTEM.ADMIN.SVRCONN`, exists on every remote queue manager. You ***must*** create this channel yourself. It is mandatory for every remote queue manager being administered. Without it, remote administration is not possible.
4. Verify that the `SYSTEM.MQEXPLORER.REPLY.MODEL` queue exists.

Managing the command server for remote administration

Use this information to learn about the remote administration of IBM MQ IBM i command server.

Each queue manager can have a command server associated with it. A command server processes any incoming commands from remote queue managers, or PCF commands from applications. It presents the commands to the queue manager for processing and returns a completion code or operator message depending on the origin of the command.

A command server is mandatory for all administration involving PCFs, the MQAI, and also for remote administration.

Note: For remote administration, you must ensure that the target queue manager is running. Otherwise, the messages containing commands cannot leave the queue manager from which they are issued. Instead, these messages are queued in the local transmission queue that serves the remote queue manager. Avoid this situation if at all possible.

There are separate control commands for starting and stopping the command server. You can perform the operations described in the following sections using the IBM MQ Explorer.

Starting and stopping the command server

To start the command server, use this CL command:

```
STRMQMCSVR MQMNAME('saturn.queue.manager')
```

where `saturn.queue.manager` is the queue manager for which the command server is being started.

To stop the command server, use one of the following CL commands:

1.
   ```
   ENDMQMCSVR MQMNAME('saturn.queue.manager') OPTION(*CNTRLD)
   ```

   to perform a controlled stop, where `saturn.queue.manager` is the queue manager for which the command server is being stopped. This is the default option, which means that the `OPTION(*CNTRLD)` can be omitted.

2.
   ```
   ENDMQMCSVR MQMNAME('saturn.queue.manager') OPTION(*IMMED)
   ```

   to perform an immediate stop, where `saturn.queue.manager` is the queue manager for which the command server is being stopped.

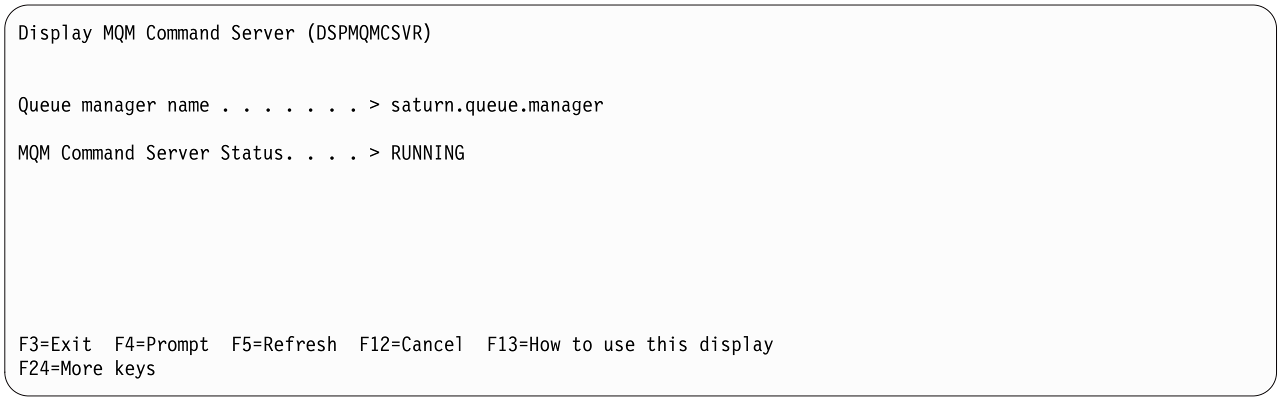
Displaying the status of the command server

For remote administration, ensure that the command server on the target queue manager is running. If it is not running, remote commands cannot be processed. Any messages containing commands are queued in the target queue manager's command queue `SYSTEM.ADMIN.COMMAND.QUEUE`.

To display the status of the command server for a queue manager, called here `saturn.queue.manager`, the CL command is:

```
DSPMQMCSVR MQMNAME('saturn.queue.manager')
```

Issue this command on the target machine. If the command server is running, the panel shown in Figure 31 appears:



```
Display MQM Command Server (DSPMQMCSVR)

Queue manager name . . . . . . . > saturn.queue.manager

MQM Command Server Status. . . . > RUNNING

F3=Exit  F4=Prompt  F5=Refresh  F12=Cancel  F13=How to use this display
F24=More keys
```

Figure 31. Display MQM Command Server panel

Work management

This information describes the way in which IBM MQ handles work requests, and details the options available for prioritizing and controlling the jobs associated with IBM MQ.

Warning

Do **not** alter IBM MQ work management objects unless you fully understand the concepts of IBM i and IBM MQ work management.

Additional information regarding subsystems and job descriptions can be found under Work Management in the IBM i product documentation. Pay particular attention to the sections on Starting jobs and Batch jobs.

IBM MQ for IBM i incorporates the IBM i UNIX environment and IBM i threads. Do **not** make any changes to the objects in the Integrated File System (IFS).

During normal operations, an IBM MQ queue manager starts a number of batch jobs to perform different tasks. By default these batch jobs run in the QMQM subsystem that is created when IBM MQ is installed.

Work management refers to the process of tailoring IBM MQ tasks to obtain the optimum performance from your system, or to make administration simpler.

For example, you can:

- Change the run-priority of jobs to make one queue manager more responsive than another.
- Redirect the output of a number of jobs to a particular output queue.
- Make all jobs of a certain type run in a specific subsystem.
- Isolate errors to a subsystem.

Work management is carried out by creating or changing the job descriptions associated with the IBM MQ jobs. You can configure work management for:

- An entire IBM MQ installation.
- Individual queue managers.
- Individual jobs for individual queue managers.

Description of IBM MQ tasks

This is a table of the IBM MQ jobs and a brief description of each.

When a queue manager is running, you see some or all of the following batch jobs running under the QMQM user profile in the IBM MQ subsystem. The jobs are described briefly in Table 7.

You can view all jobs connected to a queue manager using option 22 on the Work with Queue Manager (WRKMQM) panel. You can view listeners using the WRKMQMLSR command.

Table 7. IBM MQ tasks.

Job name	**Function**
AMQALMPX	The checkpoint processor that periodically takes journal checkpoints.
AMQZMUC0	Utility manager. This job executes critical queue manager utilities, for example the journal chain manager.
AMQZXMA0	The execution controller that is the first job started by the queue manager. It handles MQCONN requests, and starts agent processes to process IBM MQ API calls.
AMQZFUMA	Object authority manager (OAM).
AMQZLAA0	Queue manager agents that perform most of the work for applications that connect to the queue manager using MQCNO_STANDARD_BINDING.
AMQZLSA0	Queue manager agent.
AMQZMUF0	Utility Manager
AMQZMGR0	Process controller. This job is used to start up and manage listeners and services.
AMQZMUR0	Utility manager. This job executes critical queue manager utilities, for example the journal chain manager.
AMQFQPUB	Queued publish/subscribe daemon.
AMQFCXBA	Broker worker job.
RUNMQBRK	Broker control job.
AMQRMPPA	Channel process pooling job.
AMQCRSTA	TCP/IP-invoked channel responder.
AMQCRS6B	LU62 receiver channel and client connection (see note).
AMQRRMFA	Repository manager for clusters.
AMQCLMAA	Non-threaded TCP/IP listener.
AMQPCSEA	PCF command processor that handles PCF and remote administration requests.
RUNMQTRM	Trigger monitor.
RUNMQDLQ	Dead letter queue handler.
RUNMQCHI	The channel initiator.
RUNMQCHL	Sender channel job that is started for each sender channel.
RUNMQLSR	Threaded TCP/IP listener.
AMQRCMLA	Channel MQSC and PCF command processor.

Note: The LU62 receiver job runs in the communications subsystem and takes its runtime properties from the routing and communications entries that are used to start the job. See Initiated end (Receiver) for more information.

IBM MQ for IBM i work management objects

When IBM MQ is installed, various objects are supplied in the QMQM library to assist with work management. These objects are the ones necessary for IBM MQ jobs to run in their own subsystem.

Sample job descriptions are provided for two of the IBM MQ batch jobs. If no specific job description is provided for an IBM MQ job, it runs with the default job description QMQMJOBD.

The work management objects that are supplied when you install IBM MQ are listed in Table 8 and the objects created for a queue manager are listed in Table 9

Note: The work management objects can be found in the QMQM library and the queue manager objects can be found in the queue manager library.

Table 8. Work management objects

Name	Type	Description
AMQALMPX	*JOBD	The job description that is used by the checkpoint process
AMQZLAA0	*JOBD	The job description that is used by the IBM MQ agent processes
AMQZLSA0	*JOBD	The isolated bindings queue manager agent
AMQZXMA0	*JOBD	The job description that is used by IBM MQ execution controllers
QMQM	*SBSD	The subsystem in which all IBM MQ jobs run
QMQM	*JOBQ	The job queue attached to the supplied subsystem
QMQMJOBD	*JOBD	The default IBM MQ job description, used if there is not a specific job description for a job
QMQMMSG	*MSGQ	The default message queue for IBM MQ jobs.
QMQMRUN20	*CLS	A class description for high priority IBM MQ jobs
QMQMRUN35	*CLS	A class description for medium priority IBM MQ jobs
QMQMRUN50	*CLS	A class description for low priority IBM MQ jobs

Table 9. Work management objects created for a queue manager

Name	Type	Description
AMQA000000	*JRNRCV	Local journal receiver
AMQAJRN	*JRN	Local journal
AMQJRNINF	*USRSPC	User space that is updated with the latest journal receivers required for startup and media recovery of a queue manager. This user space can be queried by an application to determine which journal receivers require archiving and which can be safely deleted.
AMQAJRNMSG	*MSGQ	Local journal message queue
AMQCRC6B	*PGM	Program to start the LU6.2 connection
AMQRFOLD	*FILE	Migrated queue manager channel definition file
QMQMMSG	*MSGQ	Queue manager message queue

How IBM MQ uses the work management objects

This information describes the way in which IBM MQ uses the work management objects, and provides configuration examples.

Attention: Do not alter the job queue entry settings in the QMQM subsytem to limit the number of jobs allowed in the subsystem by priority. If you attempt to do this, you can stop essential IBM MQ jobs from running after they are submitted and cause the queue manager startup to fail.

To understand how to configure work management, you must first understand how IBM MQ uses job descriptions.

The job description used to start the job controls many attributes of the job. For example:

- The job queue on which the job is queued and on which subsystem the job runs.
- The routing data used to start the job and class that the job uses for its runtime parameters.
- The output queue that the job uses for print files.

The process of starting an IBM MQ job can be considered in three steps:

1. IBM MQ selects a job description.

   IBM MQ uses the following technique to determine which job description to use for a batch job:

   a. Look in the queue manager library for a job description with the same name as the job. See Understanding IBM MQ for IBM i queue manager library names for further details about the queue manager library.

   b. Look in the queue manager library for the default job description QMQMJOBD.

   c. Look in the QMQM library for a job description with the same name as the job.

   d. Use the default job description, QMQMJOBD, in the QMQM library.

2. The job is submitted to the job queue.

   Job descriptions supplied with IBM MQ have been set up, by default, to put jobs on to job queue QMQM in library QMQM. The QMQM job queue is attached to the supplied QMQM subsystem, so by default the jobs start running in the QMQM subsystem.

3. The job enters the subsystem and goes through the routing steps.

   When the job enters the subsystem, the routing data specified on the job description is used to find routing entries for the job.

   The routing data must match one of the routing entries defined in the QMQM subsystem, and this defines which of the supplied classes (QMQMRUN20, QMQMRUN35, or QMQMRUN50) is used by the job.

Note: If IBM MQ jobs do not appear to be starting, make sure that the subsystem is running and the job queue is not held,

If you have modified the IBM MQ work management objects, make sure everything is associated correctly. For example, if you specify a job queue other than QMQM/QMQM on the job description, make sure that an ADDJOBQE is performed for the subsystem, that is, QMQM.

You can create a job description for each job documented in Table 7 on page 203 using the following worksheet as an example:

```
What is the queue manager library name? __________
Does job description AMQZXMA0 exist in the queue manager library? Yes   No
Does job description QMQMJOBD exist in the queue manager library? Yes   No
Does job description AMQZXMA0 exist in the QMQM library?     Yes   No
Does job description QMQMJOBD exist in the QMQM library?     Yes   No
```

If you answer No to all these questions, create a global job description QMQMJOBD in the QMQM library.

The IBM MQ message queue

An IBM MQ message queue, QMQMMSG, is created in each queue manager library. Operating system messages are sent to this queue when queue manager jobs end and IBM MQ sends messages to the queue. For example, to report which journal receivers are needed at startup. Keep the number of messages in this message queue at a manageable size to make it easier to monitor.

Default system examples

These examples show how an unmodified IBM MQ installation works when some of the standard jobs are submitted at queue manager startup time.

First, the AMQZXMA0 execution controller job starts.

1. Issue the **STRMQM** command for queue manager `TESTQM`.
2. IBM MQ searches the queue manager library QMTESTQM, firstly for job description AMQZXMA0, and then job description QMQMJOBD.

   Neither of these job descriptions exist, so IBM MQ looks for job description AMQZXMA0 in the product library QMQM. This job description exists, so it is used to submit the job.
3. The job description uses the IBM MQ default job queue, so the job is submitted to job queue QMQM/QMQM.
4. The routing data on the AMQZXMA0 job description is QMQMRUN20, so the system searches the subsystem routing entries for one that matches that data.

   By default, the routing entry with sequence number 9900 has comparison data that matches QMQMRUN20, so the job is started with the class defined on that routing entry, which is also called QMQMRUN20.
5. The QMQM/QMQMRUN20 class has run priority set to 20, so the AMQZXMA0 job runs in subsystem QMQM with the same priority as most interactive jobs on the system.

Next, the AMQALMPX checkpoint process job starts.

1. IBM MQ searches the queue manager library QMTESTQM, firstly for job description AMQALPMX, and then job description QMQMJOBD.

   Neither of these job descriptions exist, so IBM MQ looks for job descriptions AMQALMPX and QMQMJOBD in the product library QMQM.

   Job description AMQALMPX does not exist but QMQMJOBD does, so QMQMJOBD is used to submit the job.

   Note: The QMQMJOBD job description is always used for IBM MQ jobs that do not have their own job description.
2. The job description uses the IBM MQ default job queue, so the job is submitted to job queue QMQM/QMQM.
3. The routing data on the QMQMJOBD job description is QMQMRUN35, so the system searches the subsystem routing entries for one that matches that data.

   By default, the routing entry with sequence number 9910 has comparison data that matches QMQMRUN35, so the job is started with the class defined on that routing entry, which is also called QMQMRUN35.
4. The QMQM/QMQMRUN35 class has run priority set to 35, so the AMQALMPX job runs in subsystem QMQM with a lower priority than most interactive jobs on the system, but higher priority than most batch jobs.

Configuring work management examples

Use this information to learn how you can change and create IBM MQ job descriptions to change the runtime attributes of IBM MQ jobs.

The key to the flexibility of IBM MQ work management lies in the two-tier way that IBM MQ searches for job descriptions:

- If you create or change job descriptions in a queue manager library, those changes override the global job descriptions in QMQM, but the changes are *local* and affect that particular queue manager alone.
- If you create or change global job descriptions in the QMQM library, those job descriptions affect all queue managers on the system, unless overridden locally for individual queue managers.

1. The following example increases the priority of channel control jobs for an individual queue manager.

   To make the repository manager and channel initiator jobs, AMQRRMFA and RUNMQCHI, run as quickly as possible for queue manager TESTQM, carry out the following steps:

   a. Create local duplicates of the QMQM/QMQMJOBD job description with the names of the IBM MQ processes that you want to control in the queue manager library. For example:

   ```
   CRTDUPOBJ OBJ(QMQMJOBD) FROMLIB(QMQM) OBJTYPE(*JOBD) TOLIB(QMTESTQM)
   NEWOBJ(RUNMQCHI)
   CRTDUPOBJ OBJ(QMQMJOBD) FROMLIB(QMQM) OBJTYPE(*JOBD) TOLIB(QMTESTQM)
   NEWOBJ(AMQRRMFA)
   ```

   b. Change the routing data parameter on the job description to ensure that the jobs use the QMQMRUN20 class.

   ```
   CHGJOBD JOBD(QMTESTQM/RUNMQCHI) RTGDTA('QMQMRUN20')
   CHGJOBD JOBD(QMTESTQM/AMQRRMFA) RTGDTA('QMQMRUN20')
   ```

   The AMQRRMFA and RUNMQCHI jobs for queue manager TESTQM now:

   - Use the new local job descriptions in the queue manager library
   - Run with priority 20, because the QMQMRUN20 class is used when the jobs enter the subsystem.

2. The following example defines a new run priority class for the QMQM subsystem.

   a. Create a duplicate class in the QMQM library, to allow other queue managers to access the class, by issuing the following command:

   ```
   CRTDUPOBJ OBJ(QMQMRUN20) FROMLIB(QMQM) OBJTYPE(*CLS) TOLIB(QMQM)
   NEWOBJ(QMQMRUN10)
   ```

   b. Change the class to have the new run priority by issuing the following command:

   ```
   CHGCLS CLS(QMQM/QMQMRUN10) RUNPTY(10)
   ```

   c. Add the new class definition to the subsystem by issuing the following command:

   ```
   ADDRTGE SBSD(QMQM/QMQM) SEQNBR(8999) CMPVAL('QMQMRUN10') PGM(QSYS/QCMD)
   CLS(QMQM/QMQMRUN10)
   ```

   Note: You can specify any numeric value for the routing sequence number, but the values must be in sequential order. This sequence number tells the subsystem the order in which routing entries are to be searched for a routing data match.

   d. Change the local or global job description to use the new priority class by issuing the following command:

   ```
   CHGJOBD JOBD(QMQMlibname/QMQMJOBD) RTGDTA('QMQMRUN10')
   ```

   Now all the queue manager jobs associated with the QMlibraryname use a run priority of 10.

3. The following example runs a queue manager in its own subsystem

   To make all the jobs for queue manager TESTQM run in the QBATCH subsystem, carry out the following steps:

   a. Create a local duplicate of the QMQM/QMQMJOBD job description in the queue manager library with the command

   ```
   CRTDUPOBJ OBJ(QMQMJOBD) FROMLIB(QMQM) OBJTYPE(*JOBD) TOLIB(QMTESTQM)
   ```

b. Change the job queue parameter on the job description to ensure that the jobs use the QBATCH job queue.

```
CHGJOBD JOBD(QMTESTQM/QMQMJOBD) JOBQ(*LIBL/QBATCH)
```

Note: The job queue is associated with the subsystem description. If you find that the jobs are staying on the job queue, verify that the job queue definition is defined on the SBSD. Use the DSPSBSD command for the subsystem and take option **6**, "Job queue entries".

All jobs for queue manager TESTQM now:

- Use the new local default job description in the queue manager library
- Are submitted to job queue QBATCH.

To ensure that jobs are routed and prioritized correctly:

- Either create routing entries for the IBM MQ jobs in subsystem QBATCH, or
- Rely on a catch-all routing entry that calls QCMD, irrespective of what routing data is used.

  This option works only if the maximum active jobs option for job queue QBATCH is set to *NOMAX. The system default is 1.

4. The following example creates another IBM MQ subsystem
   a. Create a duplicate subsystem in the QMQM library by issuing the following command:
   ```
   CRTDUPOBJ OBJ(QMQM) FROMLIB(QMQM) OBJTYPE(*SBSD) TOLIB(QMQM) NEWOBJ(QMQM2)
   ```
   b. Remove the QMQM job queue by issuing the following command:
   ```
   RMVJOBQE SBSD(QMQM/QMQM2) JOBQ(QMQM/QMQM)
   ```
   c. Create a new job queue for the subsystem by issuing the following command:
   ```
   CRTJOBQ JOBQ(QMQM/QMQM2) TEXT('Job queue for IBM MQ Queue Manager')
   ```
   d. Add a job queue entry to the subsystem by issuing the following command:
   ```
   ADDJOBQE SBSD(QMQM/QMQM2) JOBQ(QMQM/QMQM2) MAXACT(*NOMAX)
   ```
   e. Create a duplicate QMQMJOBD in the queue manager library by issuing the following command:
   ```
   CRTDUPOBJ OBJ(QMQMJOBD) FROMLIB(QMQM) OBJTYPE(*JOBD) TOLIB(QMlibraryname)
   ```
   f. Change the job description to use the new job queue by issuing the following command:
   ```
   CHGJOBD JOBD(QMlibraryname/QMQMJOBD) JOBQ(QMQM/QMQM2)
   ```
   g. Start the subsystem by issuing the following command:
   ```
   STRSBS SBSD(QMQM/QMQM2)
   ```

   Note:

   a. You can specify the subsystem in any library. If for any reason the product is reinstalled, or the QMQM library is replaced, any changes you made are removed.
   b. All the queue manager jobs associated with the QMlibraryname now run under subsystem QMQM2.
5. The following example collects all output for a job type.

   To collect all the checkpoint process, AMQALMPX, job logs for multiple queue managers onto a single output queue, carry out the following steps:

   a. Create an output queue, for example
   ```
   CRTOUTQ OUTQ(MYLIB/CHCKPTLOGS)
   ```
   b. Create a global duplicate of the QMQM/QMQMJOBD job description, using the name of the IBM MQ process that you want to control, for example
   ```
   CRTDUPOBJ OBJ(QMQMJOBD) FROMLIB(QMQM) OBJTYPE(*JOBD) NEWOBJ(AMQALMPX)
   ```
   c. Change the output queue parameter on the job description to point to your new output queue, and change the job logging level so that all messages are written to the job log.
   ```
   CHGJOBD JOBD(QMQM/AMQALMPX) OUTQ(MYLIB/CHKPTLOGS) LOG(4 00 *SECLVL)
   ```

All IBM MQ AMQALMPX jobs, for all queue managers, use the new global AMQALMPX job description, provided that there are no local overriding job descriptions in the local queue manager library.

All job log spool files for these jobs are now written to output queue CHKPTLOGS in library MYLIB.

Note:

a. The preceding example works only if the QPJOBLOG, or any print file, has a value of *JOB for its output queue parameter. In the preceding example, the QSYS/QPDJOBLOG file needs OUTQ set to *JOB.
b. To change a system print file, use the CHGPRTF command. For example:
```
CHGPRTF PRTF(QJOBLOG) OUTQ(*JOB)
```
   The *JOB option indicates that your job descriptions must be used.
c. You can send any spool files associated with the IBM MQ jobs to a particular output queue. However, verify that the print file being used has the appropriate value for the OUTQ parameter.

Availability, backup, recovery, and restart

Use this information to understand how IBM MQ for IBM i uses the IBM i journaling support to help its backup and restore strategy.

You must be familiar with standard IBM i backup and recovery methods, and with the use of journals and their associated journal receivers on IBM i, before reading this section. For information on these topics, see Backup and recovery.

To understand the backup and recovery strategy, you first need to understand how IBM MQ for IBM i organizes its data in the IBM i file system and the integrated file system (IFS).

IBM MQ for IBM i holds its data in an individual library for each queue manager instance, and in stream files in the IFS file system.

The queue manager specific libraries contain journals, journal receivers, and objects required to control the work management of the queue manager. The IFS directories and files contain IBM MQ configuration files, the descriptions of IBM MQ objects, and the data they contain.

Every change to these objects, that is recoverable across a system failure, is recorded in a journal *before* it is applied to the appropriate object. This has the effect that such changes can be recovered by replaying the information recorded in the journal.

You can configure IBM MQ for IBM i to use multiple queue manager instances on different servers to provide increased queue manager availability and speed up recovery in the case of a server or queue manager failure.

IBM MQ for IBM i journals

Use this information to understand how IBM MQ for IBM i uses journals in its operation to control updates to local objects.

Each queue manager library contains a journal for that queue manager, and the journal has the name `QM` *GRLIB*/`AMQ` *A* `JRN`, where `QM` *GRLIB* is the name of the queue manager library, and *A* is a letter, `A` in the case of a single instance queue manager, that is unique to the queue manager instance.

`QM` *GRLIB* takes the name `QM`, followed by the name of the queue manager in a unique form. For example, a queue manager named `TEST` has a queue manager library named `QMTEST`. The queue manager library can be specified when creating a queue manager using the **CRTMQM** command.

Journals have associated journal receivers that contain the information being journaled. The receivers are objects to which information can only be appended and will fill up eventually.

Journal receivers use up valuable disk space with out-of-date information. However, you can place the information in permanent storage to minimize this problem. One journal receiver is attached to the journal at any particular time. If the journal receiver reaches its predetermined threshold size, it is detached and replaced by a new journal receiver. You can specify the threshold of journal receivers when you create a queue manager using **CRTMQM** and the **`THRESHOLD`** parameter.

The journal receivers associated with the local IBM MQ for IBM i journal exist in each queue manager library, and adopt a naming convention as follows:

`AMQ` *Arnnnnn*

where

A
: is a letter `A-Z`. It is `A` for single instance queue managers. It varies for different instances of a multi-instance queue manager.

nnnnn
: is decimal `00000 to 99999` that is incremented by 1 for the next journal in the sequence.

r
: is decimal `0 to 9`, that is incremented by 1 each time a receiver is restored.

The sequence of the journals is based on date. However, the naming of the next journal is based on the following rules:

1. `AMQArnnnnn` goes to `AMQAr(nnnnn+1)`, and `nnnnn` wraps when it reaches `99999`. For example, `AMQA099999` goes to `AMQA000000`, and `AMQA999999` goes to `AMQA900000`.
2. If a journal with a name generated by rule 1 already exists, the message `CPI70E3` is sent to the `QSYSOPR` message queue and automatic receiver switching stops.

   The currently-attached receiver continues to be used until you investigate the problem and manually attach a new receiver.
3. If no new name is available in the sequence (that is, all possible journal names are on the system) you need to do both of the following:
   a. Delete journals no longer needed (see "Journal management" on page 215).
   b. Record the journal changes into the latest journal receiver using (**`RCDMQMIMG`**) and then repeat the previous step. This allows the old journal receiver names to be reused.

The `AMQAJRN` journal uses the `MNGRCV(*SYSTEM)` option to enable the operating system to automatically change journal receivers when the threshold is reached. For more information on how the system manages receivers, see *IBM i Backup and Recovery*.

The journal receiver's default threshold value is 100,000 KB. You can set this to a larger value when you create the queue manager. The initial value of the `LogReceiverSize` attribute is written to the `LogDefaults` stanza of the `mqs.ini` file.

When a journal receiver extends beyond its specified threshold, the receiver is detached and a new journal receiver is created, inheriting attributes from the previous receiver. Changes to the `LogReceiverSize` or `LogASP` attributes after a queue manager has been created are ignored when the system automatically attaches a new journal receiver

See Changing configuration information on IBM i for further details on configuring the system.

If you need to change the size of journal receivers after the queue manager has been created, create a new journal receiver and set its owner to `QMQM` using the following commands:

```
CRTJRNRCV JRNRCV(QM GRLIB/AMQ Arnnnnn) THRESHOLD(xxxxxx) +
TEXT('MQM LOCAL JOURNAL RECEIVER')
CHGOBJOWN OBJ(QM GRLIB/AMQ Arnnnnn) OBJTYPE(*JRNRCV) NEWOWN(QMQM)
```

where

QMGRLIB
Is the name of your queue manager library

A Is the instance identifier (usually `A`).

rnnnnn
Is the next journal receiver in the naming sequence described previously

xxxxxx
Is the new receiver threshold (in KB)

Note: The maximum size of the receiver is governed by the operating system. To check this value look at the THRESHOLD keyword on the **CRTJRNRCV** command.

Now attach the new receiver to the `AMQAJRN` journal with the command:

```
CHGJRN JRN(QMGRLIB/AMQ A JRN) JRNRCV(QMGRLIB/AMQ Annnnnn)
```

See "Journal management" on page 215 for details on how to manage these journal receivers.

IBM MQ for IBM i journal usage:

Use this information to understand how IBM MQ for IBM i uses journals in its operation to control updates to local objects.

Persistent updates to message queues happen in two stages. The records representing the update are first written to the journal, then the queue file is updated.

The journal receivers can therefore become more up to date than the queue files. To ensure that restart processing begins from a consistent point, IBM MQ uses checkpoints.

A checkpoint is a point in time when the record described in the journal is the same as the record in the queue. The checkpoint itself consists of the series of journal records needed to restart the queue manager. For example, the state of all transactions (that is, units of work) active at the time of the checkpoint.

Checkpoints are generated automatically by IBM MQ. They are taken when the queue manager starts and shuts down, and after a certain number of operations are logged.

You can force a queue manager to take a checkpoint by issuing the RCDMQMIMG command against all objects on a queue manager and displaying the results, as follows:

```
RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) MQMNAME(<Q_MGR_NAME>) DSPJRNDTA(*YES)
```

As the queues handle further messages, the checkpoint record becomes inconsistent with the current state of the queues.

When IBM MQ is restarted, it locates the latest checkpoint record in the log. This information is held in the checkpoint file that is updated at the end of every checkpoint. The checkpoint record represents the most recent point of consistency between the log and the data. The data from this checkpoint is used to rebuild the queues as they existed at the checkpoint time. When the queues are re-created, the log is then played forward to bring the queues back to the state they were in before system failure or close down.

To understand how IBM MQ uses the journal, consider the case of a local queue called `TESTQ` in the queue manager `TEST`. This is represented by the IFS file:

```
/QIBM/UserData/mqm/qmgrs/TEST/queues
```

If a specified message is put on this queue, and then retrieved from the queue, the actions that take place are shown in Figure Figure 32.

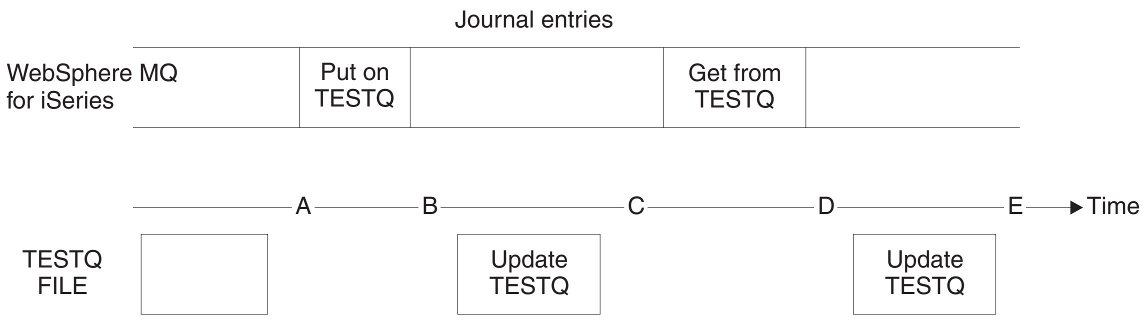


Figure 32. Sequence of events when updating MQM objects

The five points, A through E, shown in the diagram represent points in time that define the following states:

A The IFS file representation of the queue is consistent with the information contained in the journal.

B A journal entry is written to the journal defining a `Put` operation on the queue.

C The appropriate update is made to the queue.

D A journal entry is written to the journal defining a `Get` operation from the queue.

E The appropriate update is made to the queue.

The key to the recovery capabilities of IBM MQ for IBM i is that the user can save the IFS file representation of TESTQ as at time `A`, and subsequently recover the IFS file representation of TESTQ as at time `E`, by restoring the saved object and replaying the entries in the journal from time `A` onwards.

This strategy is used by IBM MQ for IBM i to recover persistent messages after system failure. IBM MQ remembers a particular entry in the journal receivers, and ensures that on startup it replays the entries in the journals from this point onwards. This startup entry is periodically recalculated so that IBM MQ only has to perform the minimum necessary replay on the next startup.

IBM MQ provides individual recovery of objects. All persistent information relating to an object is recorded in the local IBM MQ for IBM i journals. Any IBM MQ object that becomes damaged or corrupt can be completely rebuilt from the information held in the journal.

For more information on how the system manages receivers, see "Availability, backup, recovery, and restart" on page 209.

Media images:

Use this information to understand media images, and recovery from media images.

An IBM MQ object of long duration can represent a large number of journal entries, going back to the point at which it was created. To avoid this, IBM MQ for IBM i has the concept of a *media image* of an object.

This media image is a complete copy of the IBM MQ object recorded in the journal. If an image of an object is taken, the object can be rebuilt by replaying journal entries from this image onwards. The entry in the journal that represents the replay point for each IBM MQ object is referred to as its *media recovery entry*. IBM MQ keeps track of the:

- Media recovery entry for each queue manager object.
- Oldest entry from within this set (see error message AMQ7462 in "Journal management" on page 215 for details.

Images of the *CTLG object and the *MQM object are taken regularly because these objects are crucial to queue manager restart.

Images of other objects are taken when convenient. By default, images of **all** objects are taken when a queue manager is shut down using the **ENDMQM** command with parameter ENDCCTJOB(*YES). This operation can take a considerable amount of time for very large queue managers. If you need to shut down quickly, specify parameter RCDMQMIMG(*NO) with ENDCCTJOB(*YES). In such cases, you are recommended to record a complete media image in the journals after the queue manager has been restarted, using the following command:

```
RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) MQMNAME(<Q_MGR_NAME>)
```

IBM MQ automatically records an image of an object, if it finds a convenient point at which an object can be compactly described by a small entry in the journal. However, this might never happen for some objects, for example, queues that consistently contain large numbers of messages.

Rather than allow the date of the oldest media recovery entry to continue for an unnecessarily long period, use the IBM MQ command `RCDMQMIMG`, which enables you to take an image of selected objects manually.

Recovery from media images

IBM MQ automatically recovers some objects from their media image if it is found that they are corrupt or damaged. In particular, this applies to the special *MQM and *CTLG objects as part of the normal queue manager startup. If any syncpoint transaction was incomplete at the time of the last shutdown of the queue manager, any queue affected is also recovered automatically, in order to complete the startup operation.

You must recover other objects manually, using the IBM MQ command `RCRMQMOBJ`. This command replays the entries in the journal to re-create the IBM MQ object. Should an IBM MQ object become damaged, the only valid actions are to delete it or re-create it by this method. Note, however, that nonpersistent messages cannot be recovered in this fashion.

Checkpoints:

Checkpoints are taken at various times to provide a known consistent start point for recovery.

The checkpoint process AMQALMPX is responsible for taking the checkpoint at the following points:
- Queue manager startup (STRMQM).
- Queue manager shutdown (ENDMQM).
- After a period of time has elapsed since the last checkpoint (the default period is 30 minutes) and a minimum number of log records have been written since the previous checkpoint (the default value is 100).
- After a number of log records have been written. The default value is 10 000.
- After the journal threshold size has been exceeded and a new journal receiver has been automatically created.
- When a full media image is taken with:
  ```
  RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) MQMNAME(<Q_MGR_NAME>) DSPJRNDTA(*YES)
  ```

Backups of IBM MQ for IBM i data

Use this information to understand the two types of IBM MQ backup for each queue manager.

For each queue manager, there are two types of IBM MQ backup to consider:
- Data and journal backup.

  To ensure that both sets of data are consistent, do this only after shutting down the queue manager.
- Journal backup.

  You can do this while the queue manager is active.

For both methods, you need to find the names of the queue manager IFS directory and the queue manager library. You can find these in the IBM MQ configuration file (mqs.ini). For more information, see The QueueManager stanza.

Use the following procedures to do both types of backup:

Data and journal backup of a particular queue manager

Note: Do not use a save-while-active request when the queue manager is running. Such a request cannot complete unless all commitment definitions with pending changes are committed or rolled back. If this command is used when the queue manager is active, the channel connections might not end normally. Always use the following procedure.

1. Create an empty journal receiver, using the command:
   ```
   CHGJRN JRN(QMTEST/AMQAJRN) JRNRCV(*GEN)
   ```
2. Use the **RCDMQMIMG** command to record an MQM image for all IBM MQ objects, and then force a checkpoint using the command:
   ```
   RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) DSPJRNDTA(*YES) MQMNAME(TEST)
   ```
3. End channels and ensure that the queue manager is not running. If your queue manager is running, stop it with the **ENDMQM** command.
4. Backup the queue manager library by issuing the following command:
   ```
   SAVLIB LIB(QMTEST)
   ```
5. Back up the queue manager IFS directories by issuing the following command:
   ```
   SAV DEV(...) OBJ(('/QIBM/UserData/mqm/qmgrs/test'))
   ```

Journal backup of a particular queue manager

Because all relevant information is held in the journals, as long as you perform a full save at some time, partial backups can be performed by saving the journal receivers. These record all changes since the time of the full backup and are performed by issuing the following commands:

1. Create an empty journal receiver, using the command:
   ```
   CHGJRN JRN(QMTEST/AMQAJRN) JRNRCV(*GEN)
   ```
2. Use the **RCDMQMIMG** command to record an MQM image for all IBM MQ objects, and then force a checkpoint using the command:
   ```
   RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) DSPJRNDTA(*YES) MQMNAME(TEST)
   ```
3. Save the journal receivers using the command:
   ```
   SAVOBJ OBJ(AMQ*) LIB(QMTEST) OBJTYPE(*JRNRCV) .........
   ```

A simple backup strategy is to perform a full backup of the IBM MQ libraries every week, and perform a daily journal backup. This, of course, depends on how you have set up your backup strategy for your enterprise.

Journal management:

As part of your backup strategy, take care of your journal receivers. It is useful to remove journal receivers from the IBM MQ libraries for various reasons:
- To release space; this applies to all journal receivers
- To improve the performance when starting (STRMQM)
- To improve the performance of recreating objects (RCRMQMOBJ)

Before deleting a journal receiver, you must take care that you have a backup copy and that you no longer need the journal receiver.

Journal receivers can be removed from the queue manager library *after* they have been detached from the journals and saved, provided that they are available for restoration if needed for a recovery operation.

The concept of journal management is shown in Figure 33 on page 216.

Figure 33. IBM MQ for IBM i journaling

It is important to know how far back in the journals IBM MQ is likely to need to go, in order to determine when a journal receiver that has been backed up can be removed from the queue manager library, and when the backup itself can be discarded.

IBM MQ issues two messages to the queue manager message queue (QMQMMSG in the queue manager library) to help determine this time. These messages are issued when it starts, when it changes a local journal receiver, and you use RCDMQIMG to force a checkpoint. The two messages are:

AMQ7460
: Startup recovery point. This message defines the date and time of the startup entry from which IBM MQ replays the journal in the event of a startup recovery pass. If the journal receiver that contains this record is available in the IBM MQ libraries, this message also contains the name of the journal receiver containing the record.

AMQ7462
: Oldest media recovery entry. This message defines the date and time of the oldest entry to use to re-create an object from its media image.

  The journal receiver identified is the oldest one required. Any other IBM MQ journal receivers with older creation dates are no longer needed. If only stars are displayed, you need to restore backups from the date indicated to determine which is the oldest journal receiver.

When these messages are logged, IBM MQ also writes a user space object to the queue manager library that contains only one entry: the name of the oldest journal receiver that needs to be kept on the system. This user space is called AMQJRNINF, and the data is written in the format:

```
JJJJJJJJJJLLLLLLLLLLYYYYMMDDHHMMSSmmm
```

where:

`JJJJJJJJJJ`	Is the oldest receiver name that IBM MQ still needs.
`LLLLLLLLLL`	Is the journal receiver library name.
`YYYY`	Is the year of the oldest journal entry that IBM MQ needs.
`MM`	Is the month of the oldest journal entry that IBM MQ needs.
`DD`	Is the day of the oldest journal entry that IBM MQ needs.
`HH`	Is the hour of the oldest journal entry that IBM MQ needs.
`SS`	Is the seconds of the oldest journal entry that IBM MQ needs.
`mmm`	Is the milliseconds of the oldest journal entry that IBM MQ needs.

When the oldest journal receiver has been deleted from the system, this user space contains asterisks (*) for the journal receiver name.

Note: Periodically performing `RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) DSPJRNDTA(*YES)` can save startup time for IBM MQ and reduce the number of local journal receivers you need to save and restore for recovery.

IBM MQ for IBM i does not refer to the journal receivers unless it is performing a recovery pass either for startup, or for recreating an object. If it finds that a journal it requires is not present, it issues message `AMQ7432` to the queue manager message queue (QMQMMSG), reporting the time and date of the journal entry it requires to complete the recovery pass.

If this happens, restore all journal receivers that were detached after this date from the backup, to allow the recovery pass to succeed.

Keep the journal receiver that contains the startup entry, and any subsequent journal receivers, available in the queue manager library.

Keep the journal receiver containing the oldest `Media Recovery Entry`, and any subsequent journal receivers, available at all times, and either present in the queue manager library or backed-up.

When you force a checkpoint:
- If the journal receiver named in AMQ7460 is not advanced, this indicates that there is an incomplete unit of work that needs to be committed or rolled back.
- If the journal receiver named in AMQ7462 is not advanced, this indicates that there are one or more damaged objects.

Restoring a complete queue manager (data and journals):

Use this information to restore one or more queue managers from a backup or from a remote machine.

If you need to recover one or more IBM MQ queue managers from a backup, perform the following steps.

1. Quiesce the IBM MQ queue managers.
2. Locate your latest backup set, consisting of your most recent full backup and subsequently backed up journal receivers.
3. Perform a RSTLIB operation, from the full backup, to restore the IBM MQ data libraries to their state at the time of the full backup, by issuing the following commands:
   ```
   RSTLIB LIB(QMQRLIB1) .........
   RSTLIB LIB(QMQRLIB2) .........
   ```
   If a journal receiver was partially saved in one journal backup, and fully saved in a subsequent backup, restore only the fully saved one. Restore journals individually, in chronological order.
4. Perform an RST operation to restore the IBM MQ IFS directories to the IFS file system, using the following command:
   ```
   RST DEV(...) OBJ(('/QIBM/UserData/mqm/qmgrs/testqm')) ...
   ```
5. Start the message queue manager. This replays all journal records written since the full backup and restores all the IBM MQ objects to the consistent state at the time of the journal backup.

If you want to restore a complete queue manager on a different machine, use the following procedure to restore everything from the queue manager library. (We use TEST as the sample queue manager name.)

1. `CRTMQM TEST`
2. `DLTLIB LIB(QMTEST)`
3. `RSTLIB SAVLIB(QMTEST) DEV(*SAVF) SAVF(QMGRLIBSAV)`
4. Delete the following IFS files:
   ```
   /QIBM/UserData/mqm/qmgrs/TEST/QMQMCHKPT
   /QIBM/UserData/mqm/qmgrs/TEST/qmanager/QMQMOBJCAT
   /QIBM/UserData/mqm/qmgrs/TEST/qmanager/QMANAGER
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.AUTH.DATA.QUEUE/q
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.CHANNEL.INITQ/q
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.CLUSTER.COMMAND.QUEUE/q
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.CLUSTER.REPOSITORY.QUEUE/q
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.CLUSTER.TRANSMIT.QUEUE/q
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.PENDING.DATA.QUEUE/q
   /QIBM/UserData/mqm/qmgrs/TEST/queues/SYSTEM.ADMIN.COMMAND.QUEUE/q
   ```
5. `STRMQM TEST`
6. `RCRMQMOBJ OBJ(*ALL) OBJTYPE(*ALL) MQMNAME(TEST)`

Restoring journal receivers for a particular queue manager:

Use this information to understand the different ways to restore journal receivers.

The most common action is to restore a backed-up journal receiver to a queue manager library, if a receiver that has been removed is needed again for a subsequent recovery function.

This is a simple task, and requires the journal receivers to be restored using the standard IBM i RSTOBJ command:

```
RSTOBJ OBJ(QMQMDATA/AMQA000005) OBJTYPE(*JRNRCV) .........
```

A series of journal receivers might need to be restored, rather than a single receiver. For example, `AMQA000007` is the oldest receiver in the IBM MQ libraries, and both `AMQA000005` and `AMQA000006` need to be restored.

In this case, restore the receivers individually in reverse chronological order. This is not always necessary, but is good practice. In severe situations, you might need to use the IBM i command `WRKJRNA` to associate the restored journal receivers with the journal.

When restoring journals, the system automatically creates an attached journal receiver with a new name in the journal receiver sequence. However, the new name generated might be the same as a journal receiver you need to restore. Manual intervention is needed to overcome this problem; to create a new name journal receiver in sequence, and new journal before restoring the journal receiver.

For example, consider the problem with saved journal AMQAJRN and the following journal receivers:
- AMQA000000
- AMQA100000
- AMQA200000
- AMQA300000
- AMQA400000
- AMQA500000
- AMQA600000
- AMQA700000
- AMQA800000
- AMQA900000

When restoring journal AMQAJRN to a queue manager library, the system automatically creates journal receiver AMQA000000. This automatically generated receiver conflicts with one of the existing journal receivers (AMQA000000) you want to restore, which you cannot restore.

The solution is:
1. Manually create the next journal receiver (see "IBM MQ for IBM i journals" on page 210):
   ```
   CRTJRNRCV JRNRCV(QMQRLIB/AMQA900001) THRESHOLD(XXXXX)
   ```
2. Manually create the journal with the journal receiver:
   ```
   CRTJRN JRN(QMGRLIB/AMQAJRN) MNGRCV(*SYSTEM) +
   JRNRCV(QMGRLIB/AMQA9000001) MSGQ(QMGRLIB/AMQAJRNMSG)
   ```
3. Restore the local journal receivers AMQA000000 to AMQA900000.

Multi-instance queue managers

Multi-instance queue managers improve availability by automatically switching to a standby server if the active server fails. The active and standby servers are multiple instances of the same queue manager; they share the same queue manager data. If the active instance fails you need to transfer its journal to the standby that takes over so that the queue manager can rebuild its queues.

Configure the IBM i systems you are running multi-instance queue managers on so that, if the active queue manager instance fails, the journal it is using is available to the standby instance that takes over. You can design your own configuration and administration tasks to make the journal from the active instance available to the instance that takes over. If you do not want to lose messages, your design must ensure the standby journal is consistent with the active journal at the point of failure. You can adapt your design from one of the two configurations that are described with examples in subsequent topics that do maintain consistency.

1. Mirror the journal from the system that is running the active queue manager instance to the systems that are running standby instances.
2. Place the journal in an Independent Auxiliary Storage Pool (IASP) that is transferable from the system running the active instance to a standby instance.

The first solution requires no additional hardware or software as it uses basic ASPs. The second solution requires switchable IASPs which need IBM i clustering support that is available as a separately priced IBM i License Product 5761-SS1 Option 41.

Reliability and availability:

Multi-instance queue managers aim to improve the availability of applications. Technological and physical constraints mean you need different solutions to meet the demands of disaster recovery, backing up queue managers and continuous operation.

In configuring for reliability and availability you trade off a large number of factors, resulting in four distinct design points:

Disaster recovery
: Optimized for recovery after a major disaster that destroys all your local assets.

  Disaster recovery on IBM i is often based on geographic mirroring of IASP.

Backup
: Optimized for recovery after a localized failure, commonly a human error or some unforeseen technical problem.

  IBM MQ provides backup queue managers to back up queue managers periodically. You could also use asynchronous replication of queue manager journals to improve the currency of the backup.

Availability
: Optimized for restoring operations quickly giving the appearance of a nearly uninterrupted service following foreseeable technical failures such as a server or disk failure.

  Recovery is typically measured in minutes, with detection sometimes taking longer than the recovery process. A multi-instance queue manager assists you in configuring for *availability*.

Continuous operation
: Optimized for providing an uninterrupted service.

  Continuous operation solutions have to solve the detection problem, and nearly always involve submitting the same work through more than one system and either using the first result, or if correctness is a major consideration, comparing at least two outcomes.

A multi-instance queue manager assists you in configuring for *availability*. One instance of the queue manager is active at a time. Switching over to a standby instance takes from a little more than ten seconds to a fifteen minutes or more, depending on how the system is configured, loaded and tuned.

A multi-instance queue manager can give the appearance of a nearly uninterrupted service if used with reconnectable IBM MQ MQI clients, which are able to continue processing without the application program necessarily being aware of a queue manager outage; see the topic Automated client reconnection.

Components of a high availability solution:

Construct a high availability solution using multi-instance queue managers by providing robust networked storage for queue manager data, journal replication or robust IASP storage for queue manager journals, and using reconnectable clients, of applications configured as restartable queue manager services.

A multi-instance queue manager reacts to the detection of queue manager failure by resuming the startup of another queue manager instance on another server. To complete its startup, the instance needs access to the shared queue manager data in networked storage, and to its copy of the local queue manager journal.

To create a high availability solution, you need to manage the availability of the queue manager data, the currency of the local queue manager journal, and either build reconnectable client applications, or deploy your applications as queue manager services to restart automatically when the queue manager resumes. Automatic client reconnect is not supported by IBM MQ classes for Java.

Queue manager data

Place queue manager data onto networked storage that is shared, highly available and reliable, possibly by using RAID level 1 disks or greater. The file system needs to meet the requirements for a shared file system for multi-instance queue managers; for more information about the requirements for shared file systems, see Requirements for shared file systems. Network File System Version 4 (NFS4) is a protocol that meets these requirements.

Queue manager journals

You also need to configure the IBM i journals used by the queue manager instances so that the standby instance is able to restore its queue manager data to a consistent state. For uninterrupted service, this means you must restore the journals to their state when the active instance failed. Unlike backup or disaster recovery solutions, restoring journals to an earlier checkpoint is not sufficient.

You cannot physically share journals between multiple IBM i systems on networked storage. To restore queue manager journals to the consistent state at the point of failure, you either need to transfer the physical journal that was local to the active queue manager instance at the time of failure to the new instance that has been activated, or a maintain mirrors of the journal on running standby instances. The mirrored journal is a remote journal replica that has been kept exactly in sync with the local journal belonging to the failed instance.

Three configurations are starting points for designing how you manage the journals for a multi-instance queue manager,

1. Using synchronized journal replication (journal mirroring) from the active instance ASP, to the standby instances ASPs.
2. Transferring an IASP you have configured to hold the queue manager journal from the active instance to the standby instance that is taking over as the active instance.
3. Using synchronized secondary IASP mirrors.

See ASP options, for more information on putting queue manager data onto an iASP, in the IBM MQ IBM i CRTMQM command.

Also, see High availability in the IBM i Knowledge Center, and Administrator > High Availability.

Applications

To build a client to automatically reconnect to the queue manager when the standby queue manager resumes, connect your application to the queue manager using MQCONNX and specify `MQCNO_RECONNECT_Q_MGR` in the **`MQCNO`** `Options` field. See, High availability sample programs for three sample programs using reconnectable clients, and Application recovery for information about designing client applications for recovery.

Creating a network share for queue manager data using NetServer:

Create a network share on an IBM i server for storing queue manager data. Set up connections from two servers, which are going to host queue manager instances, to access the network share.

Before you begin

- You require three IBM i servers for this task. The network share is defined on one of the servers, GAMMA. The other two servers, ALPHA and BETA, are to connect to GAMMA.
- Install IBM MQ on all three servers.
- Install the System i® Navigator; see System i Navigator.

About this task

- Create the queue manager directory on GAMMA and set the correct ownership and permissions for the user profiles `QMQM` and `QMQMADM`. The directory and permission are easily created by installing IBM MQ on GAMMA.
- Use System i Navigator to create a share to the queue manager data directory on GAMMA.
- Create directories on ALPHA and BETA that point to the share.

Procedure

1. On GAMMA, create the directory to host the queue manager data with the `QMQM` user profile as the owner, and `QMQMADM` as the primary group.

   Tip:

   A quick and reliable way to create the directory with the right permissions is to install IBM MQ on GAMMA.

   Later, if you do not want to run IBM MQ on GAMMA, uninstall IBM MQ. After uninstallation, the directory `/QIBM/UserData/mqm/qmgrs` remains on GAMMA with the owner `QMQM` user profile, and `QMQMADM` the primary group.

   The task uses the `/QIBM/UserData/mqm/qmgrs` directory on GAMMA for the share.
2. Start the System i Navigator **Add connection** wizard and connect to the GAMMA system.
   a. Double-click the **System i Navigator** icon on your Windows desktop.
   b. Click **Yes** to create a connection.
   c. Follow the instructions in the **Add Connection** wizard and create a connection from the IBM i system to GAMMA.
      The connection to GAMMA is added to **My Connections**.
3. Add a new file share on GAMMA.

   a. In the System i Navigator window, click the `File Shares` folder in `My Connections/GAMMA/File Systems`.
   b. In the My Tasks window, click **Manage IBM i NetServer shares**.

      A new window, IBM i NetServer - GAMMA, opens on your desktop and shows shared objects.
   c. Right-click the `Shared Objects` folder> **File** > **New** > **File**.

      A new window, IBM i NetServer File Share - GAMMA, opens.
   d. Give the share a name, `WMQ` for example.
   e. Set the access control to `Read/Write`.
   f. Select the **Path name** by browsing to the `/QIBM/UserData/mqm/qmgrs` directory you created earlier, and click **OK**.

      The IBM i NetServer File Share - GAMMA window closes, and `WMQ` is listed in the shared objects window.
4. Right click **WMQ** in the shared objects window. Click **File** > **Permissions**.

   A window opens, Qmgrs Permissions - GAMMA, for the object `/QIBM/UserData/mqm/qmgrs`.
   a. Check the following permissions for `QMQM`, if they are not already set:
      ```
      Read
      Write
      Execute
      Management
      Existence
      Alter
      Reference
      ```
   b. Check the following permissions for `QMQMADM`, if they are not already set:
      ```
      Read
      Write
      Execute
      Reference
      ```
   c. Add other user profiles that you want to give permissions to `/QIBM/UserData/mqm/qmgrs`.

      For example, you might give the default user profile (Public) `Read` and `Execute` permissions to `/QIBM/UserData/mqm/qmgrs`.
5. Check that all the user profiles that are granted access to `/QIBM/UserData/mqm/qmgrs` on GAMMA have the same password as they do on the servers that access GAMMA.

   In particular, ensure that the `QMQM` user profiles on other servers, which are going to access the share, have the same password as the `QMQM` user profile on GAMMA.

   Tip: Click the `My Connections/GAMMA/Users and Groups` folder in the System i Navigator to set the passwords. Alternatively, use the **`CHFUSRPRF`** and **`CHGPWD`** commands.

Results

Check you can access GAMMA from other servers using the share. If you are doing the other tasks, check you can access GAMMA from ALPHA and BETA using the path `/QNTC/GAMMA/WMQ`. If the `/QNTC/GAMMA` directory does not exist on ALPHA or BETA then you must create the directory. Depending on the NetServer domain, you might have to IPL ALPHA or BETA before creating the directory.

```
CRTDIR DIR('/QNTC/GAMMA')
```

When you have checked that you have access to `/QNTC/GAMMA/WMQ` from ALPHA or BETA, issuing the command, `CRTMQM MQMNAME('QM1') MQMDIRP('/QNTC/GAMMA/WMQ')` creates `/QIBM/UserData/mqm/qmgrs/QM1` on GAMMA.

What to do next

Create a multi-instance queue manager by following the steps in either of the tasks, "Creating a multi-instance queue manager using journal mirroring and NetServer" on page 234 or "Converting a single instance queue manager to a multi-instance queue manager using NetServer and journal mirroring" on page 238.

Fail over performance:

The time it takes to detect a queue manager instance has failed, and then to resume processing on a standby can vary between tens of seconds to fifteen minutes or more depending on the configuration. Performance needs to be a major consideration in designing and testing a high availability solution.

There are advantages and disadvantages to weigh up in deciding whether to configure a multi-instance queue manager to use journal replication, or to use an IASP. Mirroring requires the queue manager to write synchronously to a remote journal. From a hardware point of view, this need not affect performance, but from a software perspective there is a greater pathlength involved in writing to a remote journal than just to a local journal, and this might be expected to reduce the performance of a running queue manager to some extent. However, when the standby queue manager takes over, the delay in synchronizing its local journal from the remote journal maintained by the active instance before it failed, is typically small in comparison to the time it takes for IBM i to detect and transfer the IASP to the server running the standby instance of the queue manager. IASP transfer times can be as much as ten to fifteen minutes rather than being completed in seconds. The IASP transfer time depends on the number of objects that need to be *varied-on* when the IASP is transferred to the standby system and the size of the access paths, or indexes, that need to be merged.

When the standby queue manager takes over, the delay in synchronizing its local journal from the remote journal maintained by the active instance before it failed, is typically small in comparison to the time it takes for IBM i to detect and transfer the independent ASP to the server running the standby instance of the queue manager. Independent ASP transfer times can be as much as ten to fifteen minutes rather than being completed in seconds. The independent ASP transfer time depends on the number of objects that need to be *varied-on* when the independent ASP is transferred to the standby system and the size of the access paths, or indices, that need to be merged.

However, transferring the journal is not the only factor influencing the time it takes for the standby instance to fully resume. You also need to consider the time it takes for the network file system to release the lock on queue manager data that signals to the standby instance to try to continue with its start-up, and also the time it takes to recover queues from the journal so that the instance is able to start processing messages again. These other sources of delay all add to the time it takes to start a standby instance. The total time to switch over consists of the following components,

Failure detection time
: The time it takes for NFS to release the lock on the queue manager data, and the standby instance to continue its startup process.

Transfer time
: In the case of an HA cluster, the time it takes IBM i to transfer the IASP from the system hosting the active instance to the standby instance, and in the case of journal replication, the time it takes to update the local journal at the standby with the data from the remote replica.

Restart time
: The time it takes for the newly active queue manager instance to rebuild its queues from the latest checkpoint in its restored journal and to resume processing messages.

Note:

If the standby instance that has taken over is configured to synchronously replicate to the previously active instance, the startup could be delayed. The new activated instance might be unable to replicate to its remote journal, if the remote journal is on the server that hosted the previously active instance, and the server has failed.

The default time to wait for a synchronous response is one minute. You can configure the maximum delay before the replication times out. Alternatively, you can configure standby instances to start using asynchronous replication to the failed active instance. Later you switch the to synchronous replication, when the failed instance is running on standby again. The same consideration applies to using synchronous independent ASP mirrors.

You can make separate baseline measurements for these components to help you assess the overall time to failover, and to factor into your decision which configuration approach to use. In making the best configuration decision you also need to consider how other applications on the same server will failover, and whether there are backup or disaster recovery processes that already use IASP.

IASP transfer times can be shortened by tuning your cluster configuration:
1. User profiles across systems in the cluster should have the same GID and UID to eliminate the need for the vary-on process to change UIDs and GIDs.
2. Minimize the number of database objects in the system and basic user disk pools, as these need to be merged to create the cross-reference table for the disk-pool group.
3. Further performance tips can be found in the IBM Redbook, *Implementing PowerHA® for IBM i, SG24-7405*.

A configuration using basic ASPs, journal mirroring, and a small configuration should switch over in the order of tens of seconds.

Overview of combining IBM i clustering capabilities with IBM MQ clustering:

Running IBM MQ on IBM i, and exploiting the IBM i clustering capabilities can provide a more comprehensive High Availability solution, than using only IBM MQ clustering.

To have this capability, you need to set up:
1. Clusters on your IBM i machine; see “IBM i clusters”
2. An independent auxiliary storage pool (IASP), into which you move the queue manager; see “Independent auxiliary storage pools (IASPs)” on page 226
3. A cluster resource group (CRG); see “Device cluster resource groups” on page 226, in which you define the:
   - Recovery domain
   - IASP
   - Exit program; see “Device CRG exit program” on page 226

IBM i clusters

An IBM i cluster is a collection of instances, that is IBM i computers or partitions, that are logically linked together.

The purpose of this grouping is to allow for each instance to be backed up, eliminating a single point of failure and increasing application and data resiliency. With a cluster created, the various cluster resource group (CRG) types can be configured to manage applications, data, and devices in the cluster.

See Creating a cluster and the Create Cluster (CRTCLU) command for further information.

Independent auxiliary storage pools (IASPs)

An IASP is a type of user ASP that serves as an extension of single-level storage. It is a piece of storage that, due to its independence from the system storage, can be easily manipulated without having to IPL the system.

An IASP can be easily switched to another operating system instance or replicated to a target IASP on another operating system instance. Two methods can be used to switch an IASP between instances:
- The first method requires all the computers in the cluster, and the switchable disk tower containing the IASP, to be connected using a High Speed Link (HSL) loop.
- The second method requires the operating system instances to be partitions on the same IBM i computer where input/output processors (IOPs) can be switched between partitions. No special hardware is needed to be able to replicate an IASP. The replication is performed using TCP/IP over the network.

See the Configure Device ASP (CFGDEVASP) command for more information.

Device cluster resource groups

There are several types of cluster resource groups (CRGs). For more information about the different types of CRGs available, see Cluster resource group.

This topic concentrates on a device CRG. A device CRG:
- Describes and manages device resources such as independent auxiliary storage pools (IASPs).
- Defines the recovery domain of the cluster nodes
- Assigns a device, and
- Assigns the exit program that will handle cluster events.

The recovery domain denotes which cluster node will be considered as the primary node. The rest of the nodes are considered to be backups. The backup nodes are also ordered in the recovery domain, specifying which node is the first backup, the second backup, and so on, depending on how many nodes there are in the recovery domain.

In the event of a primary node failure, the exit program is run on all nodes in the recovery domain. The exit program running on the first backup can then make the necessary initializations to make this node the new primary node.

See Creating device CRGs and the Create Cluster Resource Group (CRTCRG) command for more information.

Device CRG exit program

The operating system cluster resource service calls a device CRG exit program when an event occurs in one of the nodes the recovery domain defines; for example, a failover or switchover event.

A failover event occurs when the primary node of the cluster fails and the CRGs are switched with all the resources they manage, and a switchover event occurs when a specific CRG is manually switched from the primary node to the backup node.

Either way, the exit program is in charge of initializing and starting all the programs that were running on the previous primary node, which converts the first backup node into the new primary node.

For example, with IBM MQ, the exit program should be in charge of starting the IBM MQ subsystem (QMQM), and queue managers. Queue managers should be configured to automatically start listeners and services, such as trigger monitors.

Switchable IASP configuration

IBM MQ can be set up to take advantage of the clustering capabilities of IBM i. To do this:

1. Create an IBM i cluster between the data center systems
2. Move the queue manager to an IASP.

   "Moving, or removing, a queue manager to, or from, an independent auxiliary storage pool" on page 228 contains some sample code to help you carry out this operation.
3. You need to create a CRG defining the recovery domain, the IASP, and the exit program.

   "Configuring a device cluster resource group" contains some sample code to help you carry out this operation.

Related concepts:

"Independent ASPs and high availability" on page 246
Independent ASPs enable applications and data to be moved between servers. The flexibility of independent ASPs means they are the basis for some IBM i high availability solutions. In considering whether to use an ASP or independent ASP for the queue manager journal, you should consider other high availability configuration based on independent ASPs.

Configuring a device cluster resource group:

An example program to set up a device Cluster resource group (CRG).

About this task

In the following example, note that:

- [PRIMARY SITE NAME] and [BACKUP SITE NAME] could be any two distinct strings of eight characters or fewer.
- [PRIMARY IP] and [BACKUP IP] are the IPs to be used for mirroring.

Procedure

1. Identify the name of the cluster.
2. Identify the CRG exit program name and library.
3. Determine the name of the primary node and backup nodes to be defined by this CRG.
4. Identify the IASP to be managed by this CRG, and make sure it has been created under the primary node.
5. Create a device description in the backup nodes by using the command:
   ```
    CRTDEVASP DEVD([IASP NAME]) RSRCNAME([IASP NAME])
   ```
6. Add the takeover IP address to all the nodes by using the command:
   ```
   ADDTCPIFC INTNETADR(' [TAKEOVER IP]') LIND([LINE DESC])
   SUBNETMASK('[SUBNET MASK]') AUTOSTART(*NO)
   ```
7. Start the takeover IP address only in the primary node by using the command:
   ```
   STRTCPIFC INTNETADR('[TAKEOVER IP')
   ```
8. Optional: If your IASP is switchable, call this command:
   ```
   CRTCRG CLUSTER([CLUSTER NAME]) CRG( [CRG NAME]) CRGTYPE(*DEV) EXITPGM([EXIT LIB]/[EXIT NAME])
   USRPRF([EXIT PROFILE]) RCYDMN(( [PRIMARY NODE] *PRIMARY) ([BACKUP NAME] *BACKUP))
   EXITPGMFMT(EXTP0200) CFGOBJ(([IAPS NAME] *DEVD *ONLINE '[TAKEOVER IP]')
   ```
9. Optional: If your IASP is to be mirrored, call this command:

```
CRTCRG CLUSTER([CLUSTER NAME]) CRG([CRG NAME]) CRGTYPE(*DEV) EXITPGM([EXIT LIB]/[EXIT NAME])
USRPRF([EXIT PROFILE]) RCYDMN(([PRIMARY NODE] *PRIMARY *LAST [PRIMARY SITE NAME] ('[PRIMARY IP]'))
[BACKUP NAME] *BACKUP *LAST [BACKUP SITE NAME] ('[BACKUP IP]'))) EXITPGMFMT(EXTP0200)
CFGOBJ(([IAPS NAME] *DEVD *ONLINE '[TAKEOVER IP]'))
```

Moving, or removing, a queue manager to, or from, an independent auxiliary storage pool:

An example program to move a queue manager to an independent auxiliary storage pool (IASP) and commands to remove a queue manager from an IASP.

About this task

In the following example, note that:
- [MANAGER NAME] is the name of your queue manager.
- [IASP NAME] is the name of your IASP.
- [MANAGER LIBRARY] is the name of your queue manager library.
- [MANAGER DIRECTORY] is the name of your queue manager directory.

Procedure
1. Identify your primary node and your backup nodes.
2. Carry out the following procedure on your primary node:
   a. Make sure your queue manager has ended.
   b. Make sure your IASP is `vary on` by using the command
      ```
      VRYCFG CFGOBJ([IASP NAME]) CFGTYPE(*DEV) STATUS(*ON)
      ```
   c. Create the queue managers directory under the IASP. There will be a directory under root with the name of your IASP, which is:
      ```
      QSH CMD('mkdir -p /[IASP_NAME]/QIBM/UserData/mqm/qmgrs/')
      ```
   d. Move the IFS objects of your manager to the queue managers directory you have just created under the IASP using the following command:
      ```
      QSH CMD('mv /QIBM/UserData/mqm/qmgrs/[MANAGER NAME]
      /[IASP NAME]/QIBM/UserData/mqm/qmgrs')
      ```
   e. Create a temporary save file named `MGRLIB` by using the command:
      ```
      CRTSAVF QGPL/MGRLIB
      ```
   f. Save your queue manager library to the `MGRLIB` save file, by using the following command:
      ```
      SAVLIB LIB([MANGER LIBRARY]) DEV(*SAVF) SAVF(QGPL/MGRLIB)
      ```
   g. Delete the queue manager library by using the following command, and ignore all the inquiry messages:
      ```
      DLTLIB [MANAGER LIBRARY]
      ```
   h. Restore your queue manager library to the IASP by using the following command:
      ```
      RSTLIB SAVLIB([MANAGER LIBRARY]) DEV(*SAVF) SAVF(QGPL/MGRLIB)
      RSTASPDEV([IASP NAME])
      ```
   i. Delete the temporary save file by using the following command:
      ```
      DLTF FILE(QGPL/MGRLIB)
      ```
   j. Create a symbolic link to the queue manager IFS objects under the IASP, by using the following command:
      ```
      ADDLNK OBJ('/[IASP NAME]/QIBM/UserData/mqm/qmgrs/[MANAGER NAME]')
      NEWLNK('/QIBM/UserData/mqm/qmgrs/[MANAGER NAME]')
      ```
   k. Attach to the IASP by using the following command:
      ```
      SETASPGRP [IASP NAME]
      ```
   l. Start your queue manager by using the command:

```
STRMQM [MANAGER NAME]
```

3. Carry out the following procedure on your backup node, or nodes:
   a. Create a temporary queue manager directory by using the following command:
      ```
      QSH CMD('mkdir -p /[IASP NAME]/QIBM/UserData/mqm/qmgrs/[MANAGER NAME]')
      ```
   b. Create a symbolic link to the queue manager temporary directory by using the following command:
      ```
      ADDLNK OBJ('/[IASP NAME]/QIBM/UserData/mqm/qmgrs/[MANAGER NAME]')
      NEWLNK('/QIBM/UserData/mqm/qmgrs/[MANAGER NAME]')
      ```
   c. Delete the temporary directory by using the following command:
      ```
      QSH CMD('rm -r /[IASP NAME]')
      ```
   d. Add the following at the end of the file `/QIBM/UserData/mqm/mqs.ini`:
      ```
      QueueManager:
      Name=[MANAGER NAME]
      Prefix=/QIBM/UserData/mqm
      Library=[MANAGER LIBRARY]
      Directory=[MANAGER DIRECTORY]
      ```
4. To remove a queue manager from an IASP, issue the following commands:
   a. VRYCFG CFGOBJ([IASP NAME]) CFGTYPE(*DEV) STATUS(*ON)
   b. SETASPGRP [IASP NAME]
   c. ENDMQM [MANAGER NAME]
   d. DLTMQM [MANAGER NAME]

Mirrored journal configuration for ASP:

Configure a robust multi-instance queue manager using synchronous replication between mirrored journals.

A mirrored queue manager configuration uses journals that are created in basic or independent auxiliary storage pools (ASP).

On IBM i, queue manager data is written to journals and to a file system. Journals contain the master copy of queue manager data. Journals are shared between systems using either synchronous or asynchronous journal replication. A mix of local and remote journals are required to restart a queue manager instance. Queue manager restart reads journal records from the mix of local and remote journals on the server, and the queue manager data on the shared network file system. The data in the file system speeds up restarting the queue manager. Checkpoints are stored in the file system, marking points of synchronization between the file system and the journals. Journal records stored before the checkpoint are not required for typical queue manager restarts. However, the data in the file system might not be up to date, and journal records after the checkpoint are used to complete the queue manager restart. The data in the journals attached to the instance are kept up to date so that the restart can complete successfully.

But even the journal records might not be up to date, if the remote journal on the standby server was being asynchronously replicated, and the failure occurred before it was synchronized. In the event that you decide to restart a queue manager using a remote journal that is not synchronized, the standby queue manager instance might either reprocess messages that were deleted before the active instance failed, or not process messages that were received before the active instance failed.

Another, rare possibility, is that the file system contains the most recent checkpoint record, and an unsynchronized remote journal on the standby does not. In this case the queue manager does not restart automatically. You have a choice of waiting until the remote journal is synchronized, or cold starting the standby queue manager from the file system. Even though, in this case, the file system contains a more recent checkpoint of the queue manager data than the remote journal, it might not contain all the messages that were processed before the active instance failed. Some messages might be reprocessed, and some not processed, after a cold restart that is out of synchronization with the journals.

With a multi-instance queue manager, the file system is also used to control which instance of a queue manager is active, and which is the standby. The active instance acquires a lock to the queue manager data. The standby waits to acquire the lock, and when it does, it becomes the active instance. The lock is released by the active instance, if it ends normally. The lock is released by the file system if the file system detects the active instance has failed, or cannot access the file system. The file system must meet the requirements for detecting failure; see Requirements for shared file systems.

The architecture of multi-instance queue managers on IBM i provides automatic restart following server or queue manager failure. It also supports restoration of queue manager data following failure of the file system where the queue manager data is stored.

In Figure 34, if ALPHA fails, you can manually restart `QM1` on beta, using the mirrored journal. By adding the multi-instance queue manager capability to `QM1`, the standby instance of `QM1` resumes automatically on BETA if the active instance on ALPHA fails. `QM1` can also resume automatically if it is the server ALPHA that fails, not just the active instance of `QM1`. Once BETA becomes the host of the active queue manager instance, the standby instance can be started on ALPHA.

Figure 34 shows a configuration that mirrors journals between two instances of a queue manager using NetServer to store queue manager data. You might expand the pattern to include more journals, and hence more instances. Follow the journal naming rules explained in the topic, “IBM MQ for IBM i journals” on page 210. Currently the number of running instances of a queue manager is limited to two, one is active and one is in standby.

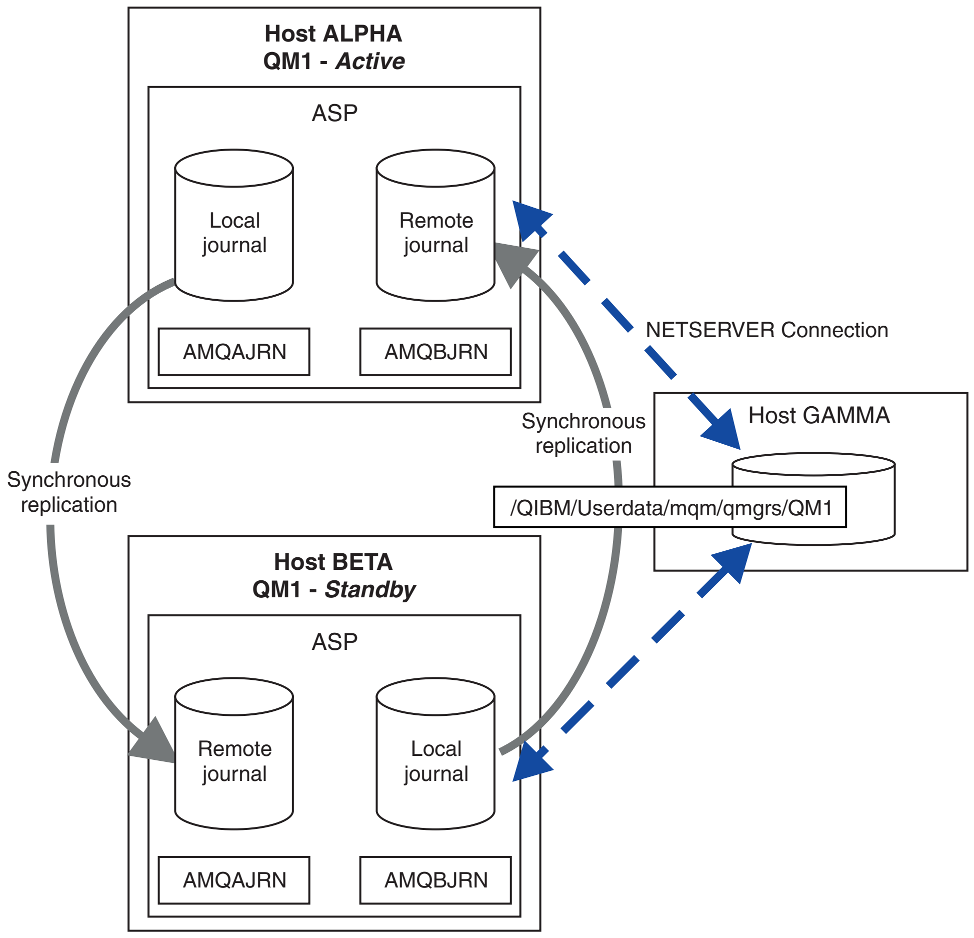

Figure 34. Mirror a queue manager journal

The local journal for QM1 on host ALPHA is called AMQAJRN (or more fully, QMQM1/AMQAJRN) and on BETA the journal is QMQM1/AMQBJRN. Each local journal replicates to remote journals on all other instances of the queue manager. If the queue manager is configured with two instances, a local journal is replicated to one remote journal.

***SYNC or *ASYNC remote journal replication**

IBM i journals are mirrored using either synchronous (*SYNC) or asynchronous (*ASYNC) journaling; see Remote journal management.

The replication mode in Figure 34 on page 230 is *SYNC, not *ASYNC. *ASYNC is faster, but if a failure occurs when the remote journal state is *ASYNCPEND, the local and remote journal are not consistent. The remote journal must catch up with the local journal. If you choose *SYNC, then the local system waits for the remote journal before returning from a call that requires a completed write. The local and remote journals generally remain consistent with one another. Only if the *SYNC operation takes longer than a designated time[1], and remote journaling is deactivated, do the journals get out of synchronization. An error is logged to the journal message queue and to QSYSOPR. The queue manager detects this message, writes an error to the queue manager error log, and deactivates remote replication of the queue manager journal. The active queue manager instance resumes without remote journaling to this journal. When the remote server is available again, you must manually reactivate synchronous remote journal replication. The journals are then resynchronized.

A problem with the *SYNC / *SYNC configuration illustrated in Figure 34 on page 230 is how the standby queue manager instance on BETA takes control. As soon as the queue manager instance on BETA writes its first persistent message, it attempts to update the remote journal on ALPHA. If the cause of control passing from ALPHA to BETA was the failure of ALPHA, and ALPHA is still down, remote journaling to ALPHA fails. BETA waits for ALPHA to respond, and then deactivates remote journaling and resumes processing messages with only local journaling. BETA has to wait a while to detect that ALPHA is down, causing a period of inactivity.

The choice between setting remote journaling to *SYNC or *ASYNC is a trade-off. Table 10 summarizes the trade-offs between using *SYNC and *ASYNC journaling between a pair of queue managers:

Table 10. Remote journaling options

Standby / Active	*SYNC	*ASYNC
***SYNC**	1. Consistent switchover and failover 2. The standby instance does not resume immediately after failover. 3. Remote journaling must be available all the time 4. Queue manager performance depends on remote journaling	1. Consistent switchover and failover 2. Remote journaling must be switched to *SYNC when standby server available 3. Remote journaling must remain available after it has been restarted 4. Queue manager performance depends on remote journaling
***ASYNC**	1. Not a sensible combination	1. Some messages might be lost or duplicated after a failover or switchover 2. Standby instance need not be available all the time for the active instance to continue without delay. 3. Performance does not depend on remote journaling

1. The designated time is 60 seconds on IBM i Version 5 and in the range 1 - 3600 seconds on IBM i 6.1 onwards.

***SYNC / *SYNC**

The active queue manager instance uses *SYNC journaling, and when the standby queue manager instance starts, it immediately tries to use *SYNC journaling.

1. The remote journal is transactionally consistent with the local journal of the active queue manager. If the queue manager is switched over to the standby instance, it can resume immediately. The standby instance normally resumes without any loss or duplication of messages. Messages are only lost or duplicated if remote journaling failed since the last checkpoint, and the previously active queue manager cannot be restarted.
2. If the queue manager fails over to the standby instance, it might not be able to start immediately. The standby queue manager instance is activated with *SYNC journaling. The cause of the failover might prevent remote journaling to the server hosting the standby instance. The queue manager waits until the problem is detected before processing any persistent messages. An error is logged to the journal message queue and to QSYSOPR. The queue manager detects this message, writes an error to the queue manager error log, and deactivates remote replication of the queue manager journal. The active queue manager instance resumes without remote journaling to this journal. When the remote server is available again, you must manually reactivate synchronous remote journal replication. The journals are then resynchronized.
3. The server to which the remote journal is replicated must always be available to maintain the remote journal. The remote journal is typically replicated to the same server that hosts the standby queue manager. The server might become unavailable. An error is logged to the journal message queue and to QSYSOPR. The queue manager detects this message, writes an error to the queue manager error log, and deactivates remote replication of the queue manager journal. The active queue manager instance resumes without remote journaling to this journal. When the remote server is available again, you must manually reactivate synchronous remote journal replication. The journals are then resynchronized.
4. Remote journaling is slower than local journaling, and substantially slower if the servers are separated by a large distance. The queue manager must wait for remote journaling, which reduces queue manager performance.

The *SYNC / *SYNC configuration between a pair of servers has the disadvantage of a delay in resuming the standby instance after failover. The *SYNC / *ASYNC configuration does not have this problem.

*SYNC / *SYNC does guarantee no message loss after switchover or failover, as long as a remote journal is available. If you want to reduce the risk of message loss after failover or switchover you have two choices. Either stop the active instance if the remote journal becomes inactive, or create remote journals on more than one server.

***SYNC / *ASYNC**

The active queue manager instance uses *SYNC journaling, and when the standby queue manager instance starts, it uses *ASYNC journaling. Shortly after the server hosting the new standby instance becomes available, the system operator must switch the remote journal on the active instance to *SYNC. When the operator switches remote journaling from *ASYNC to *SYNC the active instance pauses if the status of the remote journal is *ASYNCPEND. The active queue manager instance waits until remaining journal entries are transferred to the remote journal. When the remote journal has synchronized with the local journal, the new standby is transactionally consistent again with the new active instance. From the perspective of the management of multi-instance queue managers, in an *SYNC / *ASYNC configuration the IBM i system operator has an additional task. The operator must switch remote journaling to *SYNC in addition to restarting the failed queue manager instance.

1. The remote journal is transactionally consistent with the local journal of the active queue manager. If the active queue manager instance is switched over, or fails over to the standby instance, the standby instance can then resume immediately. The standby instance normally

resumes without any loss or duplication of messages. Messages are only lost or duplicated if remote journaling failed since the last checkpoint, and the previously active queue manager cannot be restarted.
2. The system operator must switch remote journal from `*ASYNC` to `*SYNC` shortly after the system hosting the active instance becomes available again. The operator might wait for the remote journal to catch up before switching the remote journal to `*SYNC`. Alternatively the operator might switch the remote instance to `*SYNC` immediately, and force the active instance to wait until the standby instance journal has caught up. When remote journaling is set to `*SYNC`, the standby instance is generally transactionally consistent with the active instance. Messages are only lost or duplicated if remote journaling failed since the last checkpoint, and the previously active queue manager cannot be restarted.
3. When the configuration has been restored from a switchover or failover, the server on which the remote journal is hosted must be available all the time.

Choose `*SYNC / *ASYNC` when you want the standby queue manager to resume quickly after a failover. You must restore the remote journal setting to `*SYNC` on the new active instance manually. The `*SYNC / *ASYNC` configuration matches the normal pattern of administering a pair of multi-instance queue managers. After one instance has failed, there is a time before the standby instance is restarted, during which the active instance cannot fail over.

`*ASYNC / *ASYNC`

Both the servers hosting the active and standby queue managers are configured to use `*ASYNC` remote journaling.
1. When switchover or failover take place, the queue manager continues with the journal on the new server. The journal might not be synchronized when the switchover or failover takes place. Consequently messages might be lost or duplicated.
2. The active instance runs, even if the server hosting the standby queue manager is not be available. The local journal is replicated asynchronously with the standby server when it is available.
3. The performance of the local queue manager is unaffected by remote journaling.

Choose `*ASYNC / *ASYNC` if performance is your principal requirement, and you are prepared to loose or duplicate some messages after failover or switchover.

`*ASYNC / *SYNC`

There is no reason to use this combination of options.

Queue manager activation from a remote journal

Journals are either replicated synchronously or asynchronously. The remote journal might not be active, or it might be catching up with the local journal. The remote journal might be catching up, even if it is synchronously replicated, because it might have been recently activated. The rules that the queue manager applies to the state of the remote journal it uses during start-up are as follows.
1. Standby startup fails if it must replay from the remote journal on the standby and the journal status is `*FAILED` or `*INACTPEND`.
2. When activation of the standby begins, the remote journal status on the standby must be either `*ACTIVE` or `*INACTIVE`. If the state is `*INACTIVE`, it is possible for activation to fail, if not all the journal data has been replicated.

   The failure occurs if the queue manager data on the network file system has a more recent checkpoint record than present in the remote journal. The failure is unlikely to happen, as long as the remote journal is activated well within the default 30 minute maximum interval between checkpoints. If the standby queue manager does read a more recent checkpoint record from the file system, it does not start.

   You have a choice: Wait until the local journal on the active server can be restored, or cold start the standby queue manager. If you choose to cold start, the queue manager starts with no journal data, and relies on the consistency and completeness of the queue manager data in the file system.

Note: If you cold start a queue manager, you run the risk of losing or duplicating messages after the last checkpoint. The message transactions were written to the journal, but some of the transactions might not have been written to the queue manager data in the file system. When you cold start a queue manager, a fresh journal is started, and transactions not written to the queue manager data in the file system are lost.

3. The standby queue manager activation waits for the remote journal status on the standby to change from `*ASYNCPEND` or `*SYNCPEND` to `*ASYNC` or `*SYNC`. Messages are written to the job log of the execution controller periodically.

   Note: In this case activation is waiting on the remote journal local to the standby queue manager that is being activated. The queue manager also waits for a time before continuing without a remote journal. It waits when it tries to write synchronously to its remote journal (or journals) and the journal is not available.
4. Activation stops if the journal status changes to `*FAILED` or `*INACTPEND`.

The names and states of the local and remote journals to be used in the activation are written to the queue manager error log.

Creating a multi-instance queue manager using journal mirroring and NetServer:

Create a multi-instance queue manager to run on two IBM i servers. The queue manager data is stored on a third IBM i server using NetServer. The queue manager journal is mirrored between the two servers using remote journaling. The **`ADDMQMJRN`** command is used to simplify creating the remote journals.

Before you begin

1. The task requires three IBM i servers. Install IBM MQ on two of them, ALPHA and BETA in the example. IBM MQ must be at least at version 7.0.1.1.
2. The third server is an IBM i server, connected by NetServer to ALPHA and BETA. It is used to share the queue manager data. It does not have to have an IBM MQ installation. It is useful to install IBM MQ on the server as a temporary step, to set up the queue manager directories and permissions.
3. Make sure that the `QMQM` user profile has the same password on all three servers.
4. Install IBM i NetServer; see i5/OS NetServer.

About this task

Perform the following steps to create the configuration shown in Figure 35 on page 237. The queue manager data is connected using IBM i NetServer.

- Create connections from ALPHA and BETA to the directory share on GAMMA that is to store the queue manager data. The task also sets up the necessary permissions, user profiles and passwords.
- Add Relational Database Entries (RDBE) to the IBM i systems that are going to run queue manager instances. The RDBE entries are used to connect to the IBM i systems used for remote journaling.
- Create the queue manager `QM1` on the IBM i server, ALPHA.
- Add the queue manager control information for `QM1` on the other IBM i server, BETA.
- Create remote journals on both the IBM i servers for both queue manager instances. Each queue manager writes to the local journal. The local journal is replicated to the remote journal. The command, **`ADDMQMJRN`** simplifies adding the journals and the connections.
- Start the queue manager, permitting a standby instance.

Procedure

1. Do the task, "Creating a network share for queue manager data using NetServer" on page 222.

   As a result, ALPHA and BETA have a share, `/QNTC/GAMMA/WMQ`, that points to `/QIBM/UserData/mqm/qmgrs` on GAMMA. The user profiles `QMQM` and `QMQMADM` have the necessary permissions, and `QMQM` has matching passwords on all three systems.

2. Add Relational Database Entries (RDBE) to the IBM i systems that are going to host queue manager instances.
   a. On ALPHA create the connection to BETA.
      ```
      ADDRDBDIRE RDB(BETA) RMTLOCNAME(BETA *IP) RMTAUTMTH(*USRIDPWD)
      ```
   b. On BETA create the connections to ALPHA.
      ```
      ADDRDBDIRE RDB(ALPHA) RMTLOCNAME(ALPHA *IP) RMTAUTMTH(*USRIDPWD)
      ```
3. Create the queue manager `QM1` on ALPHA, saving the queue manager data on GAMMA.
   ```
   CRTMQM MQMNAME(QM1) UDLMSGQ(SYSTEM.DEAD.LETTER.QUEUE)
   MQMDIRP(' /QNTC/GAMMA/WMQ ')
   ```
   The path, `/QNTC/GAMMA/WMQ` , uses NetServer to create the queue manager data in `/QIBM/UserData/mqm/qmgrs`.
4. Run **`ADDMQMJRN`** on ALPHA. The command adds a remote journal on BETA for `QM1`.
   ```
   ADDMQMJRN MQMNAME(QM1) RMTJRNRDB(BETA)
   ```
   `QM1` creates journal entries in its local journal on ALPHA when the active instance of `QM1` is on ALPHA. The local journal on ALPHA is replicated to the remote journal on BETA.
5. Use the command, **`DSPF`**, to inspect the IBM MQ configuration data created by **`CRTMQM`** for `QM1` on ALPHA.
   The information is needed in the next step.
   In this example, the following configuration is created in `/QIBM/UserData/mqm/mqs.ini` on ALPHA for `QM1`:
   ```
   Name=QM1
   Prefix=/QIBM/UserData/mqm
   Library=QMQM1
   Directory=QM1
   DataPath= /QNTC/GAMMA/WMQ /QM1
   ```
6. Create a queue manager instance of QM1 on BETA using the **`ADDMQMINF`** command. Run the following command on BETA to modify the queue manager control information in `/QIBM/UserData/mqm/mqs.ini` on BETA.
   ```
   ADDMQMINF MQMNAME(QM1)
   PREFIX('/QIBM/UserData/mqm')
   MQMDIR(QM1)
   MQMLIB(QMQM1)
   DATAPATH(' /QNTC/GAMMA/WMQ /QM1 ')
   ```
   Tip: Copy and paste the configuration information. The queue manager stanza is the same on ALPHA and BETA.
7. Run **`ADDMQMJRN`** on BETA. The command adds a local journal on BETA and a remote journal on ALPHA for `QM1`.
   ```
   ADDMQMJRN MQMNAME(QM1) RMTJRNRDB(ALPHA)
   ```
   `QM1` creates journal entries in its local journal on BETA when the active instance of `QM1` is on BETA. The local journal on BETA is replicated to the remote journal on ALPHA.

   Note: As an alternative, you might want to set up remote journaling from BETA to ALPHA using asynchronous journaling.

   Use this command to set up asynchronous journaling from BETA to ALPHA, instead of the command in step 7.
   ```
    ADDMQMJRN MQMNAME (QM1) RMTJRNRDB (ALPHA) RMTJRNDLV (*ASYNC)
   ```

   If the server or journaling on ALPHA is the source of the failure, BETA starts without waiting for new journal entries to be replicated to ALPHA.

   Switch the replication mode to `*SYNC`, using the **`CHGMQMJRN`** command, when ALPHA is online again.

Use the information in "Mirrored journal configuration for ASP" on page 229 to decide whether to mirror the journals synchronously, asynchronously, or a mixture of both. The default is to replicate synchronously, with a 60 second wait period for a response from the remote journal.

8. Verify that the journals on ALPHA and BETA are enabled and the status of remote journal replication is `*ACTIVE`.
   a. On ALPHA:
      ```
      WRKMQMJRN MQMNAME(QM1)
      ```
   b. On BETA:
      ```
      WRKMQMJRN MQMNAME(QM1)
      ```
9. Start the queue manager instances on ALPHA and BETA.
   a. Start the first instance on ALPHA, making it the active instance. Enabling switching over to a standby instance.
      ```
      STRMQM MQMNAME(QM1) STANDBY(*YES)
      ```
   b. Start the second instance on BETA, making it the standby instance.
      ```
      STRMQM MQMNAME(QM1) STANDBY(*YES)
      ```

Results

Use **`WRKMQM`** to check queue manager status:

1. The status of the queue manager instance on ALPHA should be `*ACTIVE`.
2. The status of the queue manager instance on BETA should be `*STANDBY`.

Example

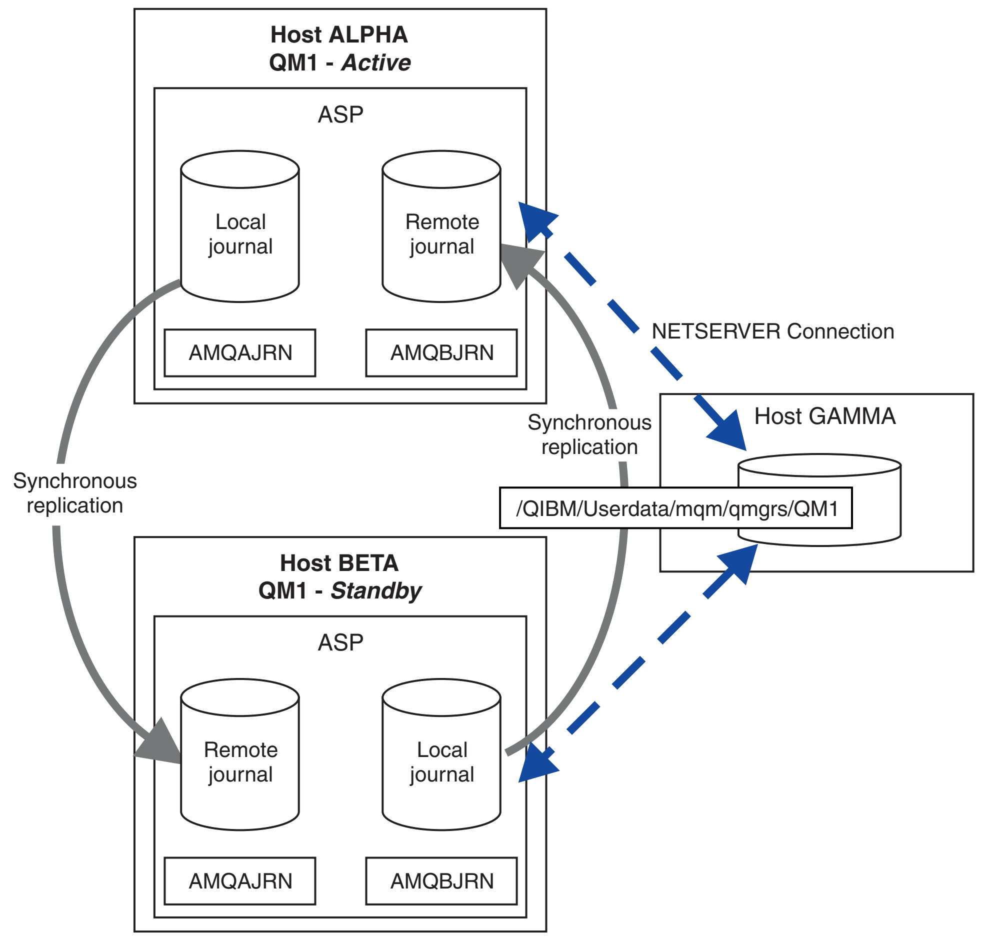

Figure 35. Mirrored journal configuration

What to do next

- Verify that the active and standby instances switch over automatically. You can run the sample high availability sample programs to test the switch over; see High availability sample programs. The sample programs are 'C' clients. You can run them from a Windows or Unix platform.
  1. Start the high availability sample programs.
  2. On ALPHA, end the queue manager requesting switch over:
     ```
     ENDMQM MQMNAME(QM1) OPTION(*IMMED) ALSWITCH(*YES)
     ```
  3. Check that the instance of QM1 on BETA is active.
  4. Restart QM1 on ALPHA
     ```
     STRMQM MQMNAME(QM1) STANDBY(*YES)
     ```
- Look at alternative high availability configurations:
  1. Use NetServer to place the queue manager data on a Windows server.
  2. Instead of using remote journaling to mirror the queue manager journal, store the journal on an independent ASP. Use IBM i clustering to transfer the independent ASP from ALPHA to BETA.

Converting a single instance queue manager to a multi-instance queue manager using NetServer and journal mirroring:

Convert a single instance queue manager to a multi-instance queue manager. Move the queue manager data to a network share connected by NetServer. Mirror the queue manager journal to a second IBM i server using remote journaling.

Before you begin

1. The task requires three IBM i servers. The existing IBM MQ installation, on the server ALPHA in the example, must be at least at Version 7.0.1.1. ALPHA is running a queue manager called `QM1` in the example.
2. Install IBM MQ on the second IBM i server, BETA in the example.
3. The third server is an IBM i server, connected by NetServer to ALPHA and BETA. It is used to share the queue manager data. It does not have to have an IBM MQ installation. It is useful to install IBM MQ on the server as a temporary step, to set up the queue manager directories and permissions.
4. Make sure that the `QMQM` user profile has the same password on all three servers.
5. Install IBM i NetServer; see i5/OS NetServer.

About this task

Perform the following steps to convert a single instance queue manager to the multi-instance queue manager shown in Figure 36 on page 241. The single instance queue manager is deleted in the task, and then recreated, storing the queue manager data on the network share connected by NetServer. This procedure is more reliable than moving the queue manager directories and files to the network share using the **`CPY`** command.

- Create connections from ALPHA and BETA to the directory share on GAMMA that is to store the queue manager data. The task also sets up the necessary permissions, user profiles and passwords.
- Add Relational Database Entries (RDBE) to the IBM i systems that are going to run queue manager instances. The RDBE entries are used to connect to the IBM i systems used for remote journaling.
- Save the queue manager logs and definitions, stop the queue manager, and delete it.
- Recreate the queue manager, storing the queue manager data on the network share on GAMMA.
- Add the second instance of the queue manager to the other server.
- Create remote journals on both the IBM i servers for both queue manager instances. Each queue manager writes to the local journal. The local journal is replicated to the remote journal. The command, **`ADDMQMJRN`** simplifies adding the journals and the connections.
- Start the queue manager, permitting a standby instance.

Note:

In step 4 on page 239 of the task, you delete the single instance queue manager, `QM1`. Deleting the queue manager deletes all the persistent messages on queues. For this reason, complete processing all the messages stored by the queue manager, before converting the queue manager. If processing all the messages is not possible, back up the queue manager library before step 4 on page 239. Restore the queue manager library after step 5 on page 239.

Note:

In step 5 on page 239 of the task, you recreate `QM1`. Although the queue manager has the same name, it has a different queue manager identifier. Queue manager clustering uses the queue manager identifier. To delete and recreate a queue manager in a cluster, you must first remove the queue manager from the cluster; see Removing a queue manager from a cluster: Alternative method or Removing a queue manager from a cluster. When you have recreated the queue manager, add it to the cluster. Although it has the same name as before, it appears to be a new queue manager to the other queue managers in the cluster.

Procedure

1. Do the task, "Creating a network share for queue manager data using NetServer" on page 222.

   As a result, ALPHA and BETA have a share, `/QNTC/GAMMA/WMQ`, that points to `/QIBM/UserData/mqm/qmgrs` on GAMMA. The user profiles `QMQM` and `QMQMADM` have the necessary permissions, and `QMQM` has matching passwords on all three systems.
2. Add Relational Database Entries (RDBE) to the IBM i systems that are going to host queue manager instances.
   a. On ALPHA create the connection to BETA.
      ```
      ADDRDBDIRE RDB(BETA) RMTLOCNAME(BETA *IP) RMTAUTMTH(*USRIDPWD)
      ```
   b. On BETA create the connections to ALPHA.
      ```
      ADDRDBDIRE RDB(ALPHA) RMTLOCNAME(ALPHA *IP) RMTAUTMTH(*USRIDPWD)
      ```
3. Create the scripts that recreate the queue manager objects.
   ```
   QSAVEQMGR LCLQMGRNAM(QM1) FILENAME('*CURLIB/QMQSC(QM1)')
   OUTPUT(*REPLACE) MAKEAUTH(*YES) AUTHFN('*CURLIB/QMAUT(QM1)')
   ```
4. Stop the queue manager and delete it.
   ```
   ENDMQM MQMNAME(QM1) OPTION(*IMMED) ENDCCTJOB(*YES) RCDMQMIMG(*YES) TIMEOUT(15)
   DLTMQM MQMNAME(QM1)
   ```
5. Create the queue manager `QM1` on ALPHA, saving the queue manager data on GAMMA.
   ```
   CRTMQM MQMNAME(QM1) UDLMSGQ(SYSTEM.DEAD.LETTER.QUEUE)
   MQMDIRP(' /QNTC/GAMMA/WMQ ')
   ```
   The path, ` /QNTC/GAMMA/WMQ `, uses NetServer to create the queue manager data in `/QIBM/UserData/mqm/qmgrs`.
6. Recreate the queue manager objects for `QM1` from the saved definitions.
   ```
   STRMQMMQSC SRCMBR(QM1) SRCFILE(*CURLIB/QMQSC) MQMNAME(QM1)
   ```
7. Apply the authorizations from the saved information.
   a. Compile the saved authorization program.
      ```
      CRTCLPGM PGM(*CURLIB/QM1) SRCFILE(*CURLIB/QMAUT)
      SRCMBR(QM1) REPLACE(*YES)
      ```
   b. Run the program to apply the authorizations.
      ```
      CALL PGM(*CURLIB/QM1)
      ```
   c. Refresh the security information for `QM1`.
      ```
      RFRMQMAUT MQMNAME(QM1)
      ```
8. Run **`ADDMQMJRN`** on ALPHA. The command adds a remote journal on BETA for `QM1`.
   ```
   ADDMQMJRN MQMNAME(QM1) RMTJRNRDB(BETA)
   ```
   `QM1` creates journal entries in its local journal on ALPHA when the active instance of `QM1` is on ALPHA. The local journal on ALPHA is replicated to the remote journal on BETA.
9. Use the command, **`DSPF`**, to inspect the IBM MQ configuration data created by **`CRTMQM`** for `QM1` on ALPHA.

   The information is needed in the next step.

   In this example, the following configuration is created in `/QIBM/UserData/mqm/mqs.ini` on ALPHA for `QM1`:
   ```
   Name=QM1
   Prefix=/QIBM/UserData/mqm
   Library=QMQM1
   Directory=QM1
   DataPath= /QNTC/GAMMA/WMQ /QM1
   ```

10. Create a queue manager instance of QM1 on BETA using the **ADDMQMINF** command. Run the following command on BETA to modify the queue manager control information in `/QIBM/UserData/mqm/mqs.ini` on BETA.

    ```
    ADDMQMINF MQMNAME(QM1)
    PREFIX('/QIBM/UserData/mqm')
    MQMDIR(QM1)
    MQMLIB(QMQM1)
    DATAPATH(' /QNTC/GAMMA/WMQ /QM1 ')
    ```

    Tip: Copy and paste the configuration information. The queue manager stanza is the same on ALPHA and BETA.
11. Run **ADDMQMJRN** on BETA. The command adds a local journal on BETA and a remote journal on ALPHA for `QM1`.

    ```
    ADDMQMJRN MQMNAME(QM1) RMTJRNRDB(ALPHA)
    ```

    `QM1` creates journal entries in its local journal on BETA when the active instance of `QM1` is on BETA. The local journal on BETA is replicated to the remote journal on ALPHA.

    Note: As an alternative, you might want to set up remote journaling from BETA to ALPHA using asynchronous journaling.

    Use this command to set up asynchronous journaling from BETA to ALPHA, instead of the command in step 7 on page 235.

    ```
     ADDMQMJRN MQMNAME (QM1) RMTJRNRDB (ALPHA) RMTJRNDLV (*ASYNC)
    ```

    If the server or journaling on ALPHA is the source of the failure, BETA starts without waiting for new journal entries to be replicated to ALPHA.

    Switch the replication mode to `*SYNC`, using the **CHGMQMJRN** command, when ALPHA is online again.

    Use the information in "Mirrored journal configuration for ASP" on page 229 to decide whether to mirror the journals synchronously, asynchronously, or a mixture of both. The default is to replicate synchronously, with a 60 second wait period for a response from the remote journal.
12. Verify that the journals on ALPHA and BETA are enabled and the status of remote journal replication is `*ACTIVE`.
    a. On ALPHA:

       ```
       WRKMQMJRN MQMNAME(QM1)
       ```
    b. On BETA:

       ```
       WRKMQMJRN MQMNAME(QM1)
       ```
13. Start the queue manager instances on ALPHA and BETA.
    a. Start the first instance on ALPHA, making it the active instance. Enabling switching over to a standby instance.

       ```
       STRMQM MQMNAME(QM1) STANDBY(*YES)
       ```
    b. Start the second instance on BETA, making it the standby instance.

       ```
       STRMQM MQMNAME(QM1) STANDBY(*YES)
       ```

Results

Use **WRKMQM** to check queue manager status:
1. The status of the queue manager instance on ALPHA should be `*ACTIVE`.
2. The status of the queue manager instance on BETA should be `*STANDBY`.

Example

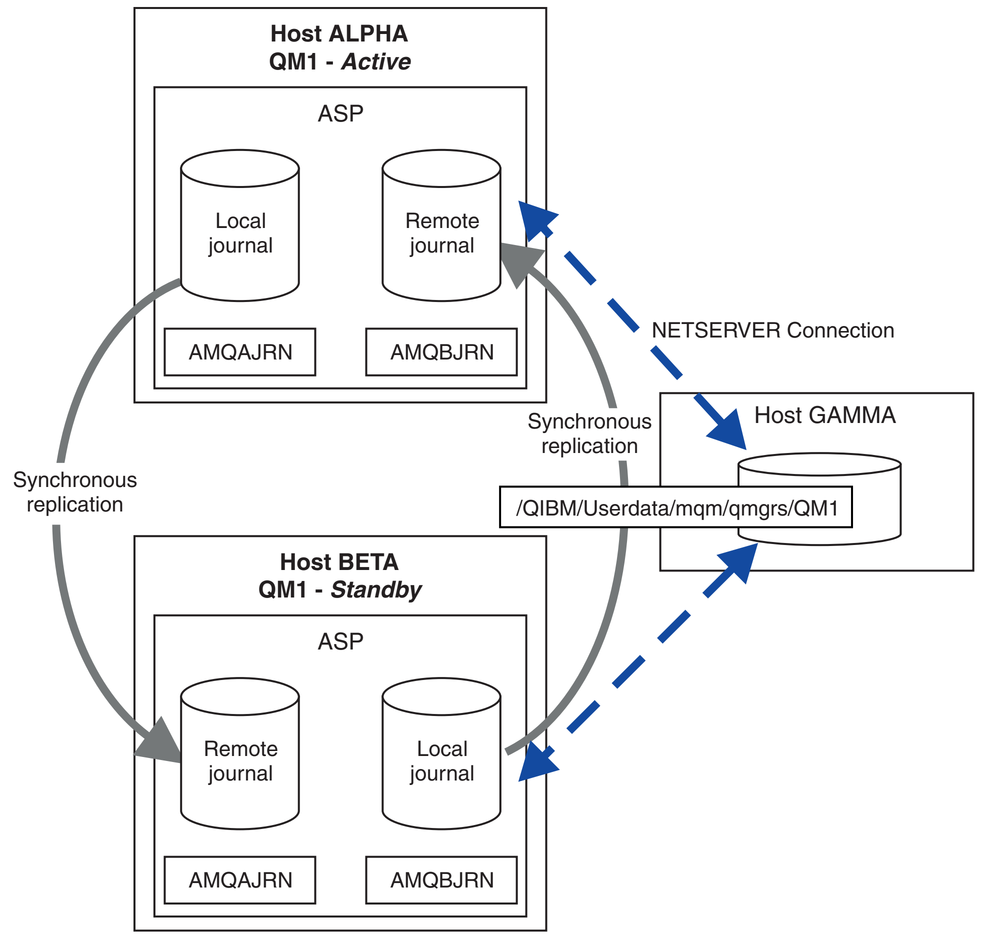

Figure 36. Mirrored journal configuration

What to do next

- Verify that the active and standby instances switch over automatically. You can run the sample high availability sample programs to test the switch over; see High availability sample programs. The sample programs are 'C' clients. You can run them from a Windows or Unix platform.
  1. Start the high availability sample programs.
  2. On ALPHA, end the queue manager requesting switch over:
     ```
     ENDMQM MQMNAME(QM1) OPTION(*IMMED) ALSWITCH(*YES)
     ```
  3. Check that the instance of `QM1` on BETA is active.
  4. Restart `QM1` on ALPHA
     ```
     STRMQM MQMNAME(QM1) STANDBY(*YES)
     ```
- Look at alternative high availability configurations:
  1. Use NetServer to place the queue manager data on a Windows server.
  2. Instead of using remote journaling to mirror the queue manager journal, store the journal on an independent ASP. Use IBM i clustering to transfer the independent ASP from ALPHA to BETA.

Switched independent ASP journal configuration:

You do not need to replicate an independent ASP journal to create a multi-instance queue manager configuration. You do need to automate a means to transfer the independent ASP from the active queue manager to the standby queue manager. There are alternative high availability solutions possible using an independent ASP, not all of which require using a multi-instance queue manager.

When using an independent ASP you do not need to mirror the queue manager journal. If you have installed cluster management, and the servers hosting the queue manager instances are in the same cluster resource group, then the queue manager journal can be transferred automatically to another server within a short distance of the active server, if the host running the active instance fails. You can also transfer the journal manually, as part of a planned switch, or you can write a command procedure to transfer the independent ASP programmatically.

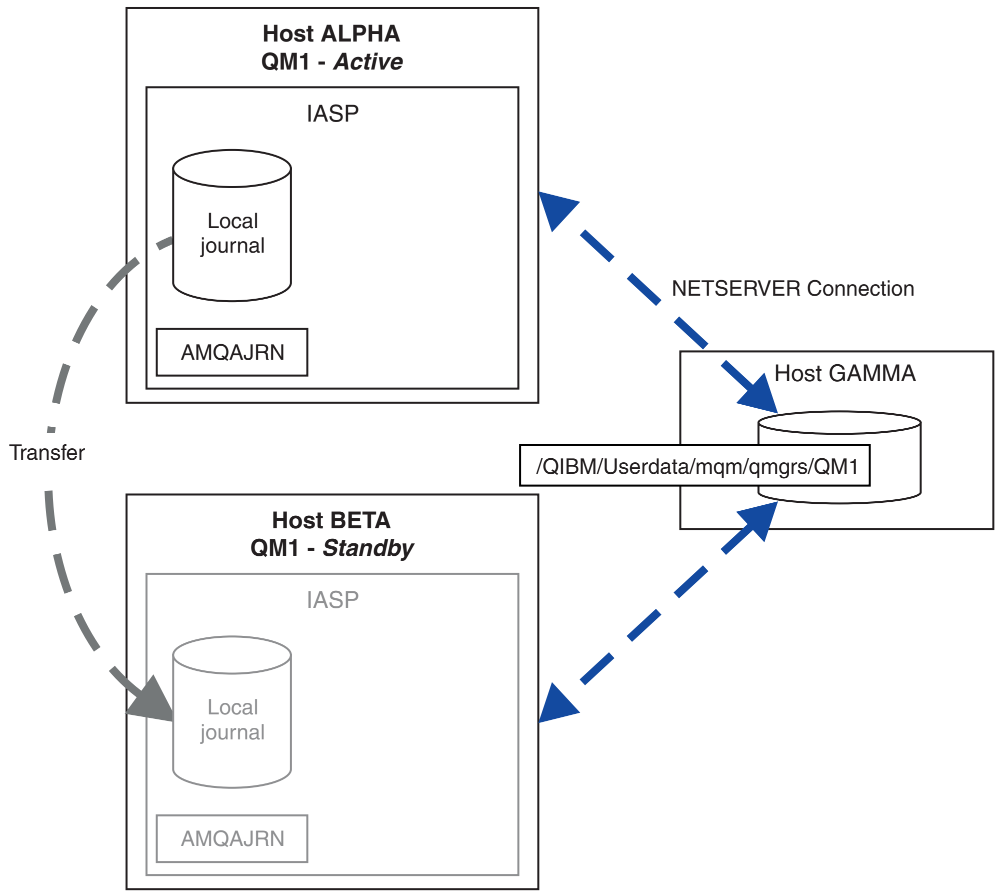

Figure 37. Transfer a queue manager journal using an independent ASP

For multi-instance queue manager operation, queue manager data must be stored on an shared file system The file system can be hosted on a variety of different platforms. You cannot store multi-instance queue manager data on an ASP or independent ASP.

The shared file system performs two roles in the configuration: The same queue manager data is shared betweem all instances of the queue manager. The file system must have a robust locking protocol that ensures only one instance of the queue manager has access to queue manager data once it has started. If the queue manager fails, or the communications to the file server breaks, then the file system must release the lock to the queue manager data held by the active instance that is no longer communicating with the file syste. The standby queue manager instance can then gain read/write access to the queue manager data. The file system protocol must conform to a set of rules to work correctly with multi-instance queue managers; see "Components of a high availability solution" on page 221.

The locking mechanism serializes the start queue manager command and controls which instance of the queue manager is active. Once a queue manager becomes active, it rebuilds its queues from the local journal that you, or the HA cluster, has transferred to the standby server. Reconnectable clients that are waiting for reconnection to the same queue manager get reconnected, and any inflight transactions are backed out. Applications that are configured to start as queue manager services are started.

You need to ensure that the local journal from the failed active queue manager instance on the independent ASP is transferred to the server that hosts the newly activated standby queue manager instance, either by configuring the cluster resource manager, or transferring the independent ASP manually. Using independent ASPs does not preclude configuring remote journals and mirroring, if you decide to use independent ASP for backup and disaster recovery, and use remote journal mirroring for multi-instance queue manager configuration.

If you have chosen to use an independent ASP, there are alternative highly available configurations you might consider. The background to these solutions are described in "Independent ASPs and high availability" on page 246.

1. Rather than use multi-instance queue managers, install and configure a single instance queue manager entirely on an independent ASP, and use IBM i high availability services to fail the queue manager over. You would probably need to augment the solution with a queue manager monitor to detect whether the queue manager has failed independently of the server. This is the basis of the solution provided in, *Supportpac MC41: Configuring IBM MQ for iSeries for High Availability*.
2. Use independent ASPs and cross site mirroring (XSM) to mirror the independent ASP rather than switching the independent ASP on the local bus. This extends the geographic range of the independent ASP solution to as far as the time taken to write log records over a long distance allows.

Creating a multi-instance queue manager using an independent ASP and NetServer:

Create a multi-instance queue manager to run on two IBM i servers. The queue manager data is stored an IBM i server using NetServer. The queue manager journal is stored on an independent ASP. Use IBM i clustering or a manual procedure to transfer the independent ASP containing the queue manager journal to the other IBM i server.

Before you begin

1. The task requires three IBM i servers. Install IBM MQ on two of them, ALPHA and BETA in the example. IBM MQ must be at least at version 7.0.1.1.
2. The third server is an IBM i server, connected by NetServer to ALPHA and BETA. It is used to share the queue manager data. It does not have to have an IBM MQ installation. It is useful to install IBM MQ on the server as a temporary step, to set up the queue manager directories and permissions.
3. Make sure that the `QMQM` user profile has the same password on all three servers.
4. Install IBM i NetServer; see i5/OS NetServer.
5. Create procedures to transfer the independent ASP from the failed queue manager to the standby that is taking over. You might find some of the techniques in *SupportPac MC41: Configuring IBM MQ for iSeries for High Availability* helpful in designing your independent ASP transfer procedures.

About this task

Perform the following steps to create the configuration shown in Figure 38 on page 245. The queue manager data is connected using IBM i NetServer.

- Create connections from ALPHA and BETA to the directory share on GAMMA that is to store the queue manager data. The task also sets up the necessary permissions, user profiles and passwords.
- Create the queue manager `QM1` on the IBM i server, ALPHA.

- Add the queue manager control information for QM1 on the other IBM i server, BETA.
- Start the queue manager, permitting a standby instance.

Procedure

1. Do the task, "Creating a network share for queue manager data using NetServer" on page 222.

   As a result, ALPHA and BETA have a share, /QNTC/GAMMA/WMQ, that points to /QIBM/UserData/mqm/qmgrs on GAMMA. The user profiles QMQM and QMQMADM have the necessary permissions, and QMQM has matching passwords on all three systems.
2. Create the queue manager QM1 on ALPHA, saving the queue manager data on GAMMA.
   ```
   CRTMQM MQMNAME(QM1) UDLMSGQ(SYSTEM.DEAD.LETTER.QUEUE)
   MQMDIRP(' /QNTC/GAMMA/WMQ ')
   ```
   The path, /QNTC/GAMMA/WMQ , uses NetServer to create the queue manager data in /QIBM/UserData/mqm/qmgrs.
3. Use the command, **DSPF**, to inspect the IBM MQ configuration data created by **CRTMQM** for QM1 on ALPHA.

   The information is needed in the next step.

   In this example, the following configuration is created in /QIBM/UserData/mqm/mqs.ini on ALPHA for QM1:
   ```
   Name=QM1
   Prefix=/QIBM/UserData/mqm
   Library=QMQM1
   Directory=QM1
   DataPath= /QNTC/GAMMA/WMQ /QM1
   ```
4. Create a queue manager instance of QM1 on BETA using the **ADDMQMINF** command. Run the following command on BETA to modify the queue manager control information in /QIBM/UserData/mqm/mqs.ini on BETA.
   ```
   ADDMQMINF MQMNAME(QM1)
   PREFIX('/QIBM/UserData/mqm')
   MQMDIR(QM1)
   MQMLIB(QMQM1)
   DATAPATH(' /QNTC/GAMMA/WMQ /QM1 ')
   ```
   Tip: Copy and paste the configuration information. The queue manager stanza is the same on ALPHA and BETA.
5. Start the queue manager instances on ALPHA and BETA.
   a. Start the first instance on ALPHA, making it the active instance. Enabling switching over to a standby instance.
   ```
   STRMQM MQMNAME(QM1) STANDBY(*YES)
   ```
   b. Start the second instance on BETA, making it the standby instance.
   ```
   STRMQM MQMNAME(QM1) STANDBY(*YES)
   ```

Results

Use **WRKMQM** to check queue manager status:

1. The status of the queue manager instance on ALPHA should be *ACTIVE.
2. The status of the queue manager instance on BETA should be *STANDBY.

Example

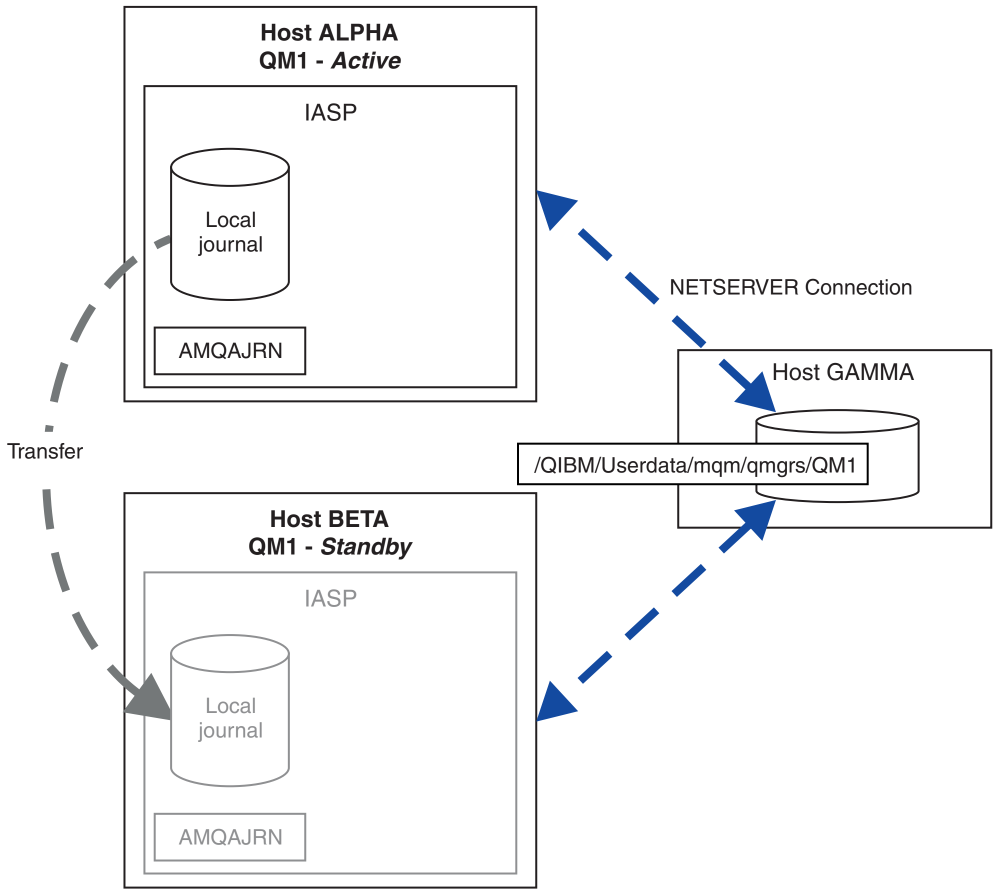

Figure 38. Transfer a queue manager journal using an independent ASP

What to do next

- Verify that the active and standby instances switch over automatically. You can run the sample high availability sample programs to test the switch over; see High availability sample programs. The sample programs are 'C' clients. You can run them from a Windows or Unix platform.
  1. Start the high availability sample programs.
  2. On ALPHA, end the queue manager requesting switch over:
     ```
     ENDMQM MQMNAME(QM1) OPTION(*IMMED) ALSWITCH(*YES)
     ```
  3. Check that the instance of QM1 on BETA is active.
  4. Restart QM1 on ALPHA
     ```
     STRMQM MQMNAME(QM1) STANDBY(*YES)
     ```
- Look at alternative high availability configurations:
  1. Use NetServer to place the queue manager data on an IBM i server.
  2. Instead of using an independent ASP to transfer the queue manager journal to the standby server, use remote journaling to mirror the journal onto the standby server.

Independent ASPs and high availability:

Independent ASPs enable applications and data to be moved between servers. The flexibility of independent ASPs means they are the basis for some IBM i high availability solutions. In considering whether to use an ASP or independent ASP for the queue manager journal, you should consider other high availability configuration based on independent ASPs.

Auxiliary storage pools (ASPs) are a building block of IBM i architecture. Disk units are grouped together to form a single ASP. By placing objects in different ASPs you can protect data in one ASP from being affected by disk failures in another ASP.

Every IBM i server has at least one *basic* ASP, known as the system ASP. It is designated as ASP1, and sometimes known as *SYSBAS. You can configure up to 31 additional basic *user* ASPs that are indistinguishable from the system ASP from the application's point of view, because they share the same namespace. By using multiple basic ASPs to distribute applications over many disks you can improve performance and reduce recovery time. Using multiple basic ASPs can also provide some degree of isolation against disk failure, but it does not improve reliability overall.

Independent ASPs are a special type of ASP. They are often called independent disk pools. Independent disk pools are key component of IBM i high availability. You can store data and applications that regard themselves as independent from the current system to which they are connected on independent disk storage units. You can configure switchable or non-switchable independent ASPs. From an availability perspective you are generally only concerned with switchable independent ASPs, which can be transferred automatically from server to server. As a result you can move the applications and data on the independent ASP from server to server.

Unlike basic user ASPs, independent ASPs do not share the same namespace as the system ASP. Applications that work with user ASPs require changes to work with an independent ASP. You need to verify your software, and third-party software you use, works in an independent ASP environment.

When the independent ASP is attached to a different server the namespace of the independent ASP has to be combined with the namespace of the system ASP. This process is called *varying-on* the independent ASP. You can vary-on an independent ASP without IPLing the server. Clustering support is required to transfer independent ASPs automatically from one server to another.

Building reliable solutions with independent ASPs

Journaling to an independent ASP, rather than journaling to an ASP and using journal replication, provides an alternative means to provide the standby queue manager with a copy of the local journal from the failed queue manager instance. To automatically transfer the independent ASP to another server you need to have installed and configured clustering support. There are a number of high-availability solutions for independent ASPs based on the cluster support, and low level disk mirroring, that you can combine with, or substitute for, using multi-instance queue managers.

The following list describes the components that are needed to build a reliable solution based on independent ASPs.

Journaling
Queue managers, and other applications, use local journals to write persistent data safely to disk to protect against loss of data in memory due to server failure. This is sometimes termed point-in-time consistency. It does not guarantee the consistency of multiple updates that take place over a period of time.

Commitment control
By using global transactions, you can coordinate updates to messages and databases so that the data written to the journal is consistent. It gives consistency over a period of time by using a two-phase commit protocol.

Switched disk

Switched disks are managed by the device cluster resource group (CRG) in an HA cluster. CRG switches independent ASPs automatically to a new server in the case of an unplanned outage. CRGs are geographically limited to the extent of the local IO bus.

By configuring your local journal on a switchable independent ASP, you can transfer the journal to a different server, and resume processing messages. No changes to persistent messages made without syncpoint control, or committed with syncpoint control, are lost, unless the independent ASP fails.

If you use both journaling and commitment control on switchable independent ASPs, you can transfer database journals and queue manager journals to a different server and resume processing transactions with no loss of consistency or committed transactions.

Cross-site mirroring (XSM)

XSM mirrors the primary independent ASP to a geographically remote secondary independent ASP across a TCP/IP network, and transfers control automatically in case of a failure. You have a choice of configuring a synchronous or asynchronous mirror. Synchronous mirroring reduces the performance of the queue manager because data is mirrored before the write operations on the production system complete, but it does guarantee the secondary independent ASP is up to date. Whereas if you use asynchronous mirroring you cannot guarantee that the secondary independent ASP is up to date. Asynchronous mirroring does maintain the consistency of the secondary independent ASP.

There are three XSM technologies.

Geographic mirroring

Geographic mirroring is an extension of clustering, enabling you to switch independent ASPs across a wide area. It has both synchronous and asynchronous modes. You can guarantee high availability only in synchronous mode, but the separation of independent ASPs might impact performance too much. You can combine geographic mirroring with switched disk to provide high availability locally and disaster recovery remotely.

Metro mirroring

Metro mirroring is a device level service that provides fast local synchronous mirroring over longer distances than the local bus. You can combine it with a multi-instance queue manager to give you high availability of the queue manager, and by having two copies of the independent ASP, high availability of the queue manager journal.

Global mirroring

Global mirroring is device level service that provides asynchronous mirroring, and is suitable for backing up and disaster recovery over longer distances, but is not an normal choice for high availability, because it only maintains point in time consistency rather than currency.

The key decision points you should consider are,

ASP or independent ASP?

You do not need to run a IBM i HA cluster to use multi-instance queue managers. You might choose independent ASPs, if you are already using independent ASPs, or you have availability requirements for other applications that require independent ASPs. It might be worth combining independent ASPs with multi-instance queue managers to replace queue manager monitoring as a means of detecting queue manager failure.

Availability?

What is the recovery time objective (RTO)? If you require the appearance of near uninterrupted behavior, then which solution has the quickest recovery time?

Journal availability?
How do you eliminate the journal as a single point of failure. You might adopt a hardware solution, using RAID 1 devices or better, or your might combine or use a software solution using replica journals or disk mirroring.

Distance?
How far apart are the active and standby queue manager instances. Can your users tolerate the performance degradation of replicating synchronously over distances greater than about 250 meters?

Skills?
There is work to be done to automate the administrative tasks involved in maintaining and exercising the solution regularly. The skills required to do the automation are different for the solutions based on ASPs and independent ASPs.

Deleting a multi-instance queue manager:

Before you delete a multi-instance queue manager, stop remote journaling, and remove queue manager instances.

Before you begin

1. In this example, two instances of the `QM1` queue manager are defined on the servers ALPHA and BETA. ALPHA is the active instance and BETA is the standby. The queue manager data associated with the queue manager `QM1` is stored on the IBM i server GAMMA, using NetServer. See "Creating a multi-instance queue manager using journal mirroring and NetServer" on page 234.
2. ALPHA and BETA must be connected so that any remote journals that are defined can be deleted by IBM MQ.
3. Verify that the `/QNTC` directory and server directory file share can be accessed, using the system commands **`EDTF`** or **`WRKLNK`**

About this task

Before you delete a multi-instance queue manager from a server using the **`DLTMQM`** command, remove any queue manager instances on other servers using the **`RMVMQMINF`** command.

When you remove a queue manager instance using the **`RMVMQMINF`** command, local and remote journals prefixed with `AMQ`, and associated with the instance, are deleted. Configuration information about the queue manager instance, local to the server, is also deleted.

Do not run the **`RMVMQMINF`** command on the server holding the remaining instance of the queue manager. Doing so prevents **`DLTMQM`** from working correctly.

Delete the queue manager using the **`DLTMQM`** command. Queue manager data is removed from the network share. Local and remote journals prefixed with `AMQ` and associated with the instance are deleted. **`DLTMQM`** also deletes configuration information about the queue manager instance, local to the server.

In the example, there are only two queue manager instances. IBM MQ supports a running multi-instance configuration that has one active queue manager instance and one standby instance. If you have created additional queue manager instances to use in running configurations, remove them, using the **`RMVMQMINF`** command, before deleting the remaining instance.

Procedure

1. Run the **`CHGMQMJRN RMTJRNSTS`** `(*INACTIVE)` command on each server to make remote journaling between the queue manager instances inactive.
   a. On ALPHA:

```
CHGMQMJRN MQMNAME('QM1')
RMTJRNRDB('BETA') RMTJRNSTS(*INACTIVE)
```

   b. On BETA:

```
CHGMQMJRN MQMNAME('QM1')
RMTJRNRDB('ALPHA') RMTJRNSTS(*INACTIVE)
```

2. Run the **ENDMQM** command on ALPHA, the active queue manager instance, to stop both instances of QM1.

   ```
   ENDMQM MQMNAME(QM1) OPTION(*IMMED) INSTANCE(*ALL) ENDCCTJOB(*YES)
   ```

3. Run the **RMVMQMINF** command on ALPHA to remove the queue manager resources for the instance from ALPHA and BETA.

   ```
   RMVMQMINF MQMNAME(QM1)
   ```

   RMVMQMINF removes the queue manager configuration information for QM1 from ALPHA. If the journal name is prefixed by AMQ, it deletes the local journal associated with QM1 from ALPHA. If the journal name is prefixed by AMQ and a remote journal has been created, it also removes the remote journal from BETA.

4. Run the **DLTMQM** command on BETA to delete QM1.

   ```
   DLTMQM MQMNAME(QM1)
   ```

   DLTMQM deletes the queue manager data from the network share on GAMMA. It removes the queue manager configuration information for QM1 from BETA. If the journal name is prefixed by AMQ, it deletes the local journal associated with QM1 from BETA. If the journal name is prefixed by AMQ and a remote journal has been created, it also removes the remote journal from ALPHA.

Results

DLTMQM and **RMVMQMINF** delete the local and remote journals created by **CRTMQM** and **ADDMQJRN**. The commands also delete the journal receivers. The journals and journal receivers must follow the naming convention of having names starting with AMQ. **DLTMQM** and **RMVMQMINF** remove the queue manager objects, queue manager data, and the queue manager configuration information from mqs.ini.

What to do next

An alternative approach is to issue the following commands after deactivating journaling in step 1 on page 248 and before ending the queue manager instances. Or, if you have not followed the naming convention, you must delete the journals and journal receivers by name.

1. On ALPHA:

   ```
   RMVMQMJRN MQMNAME('QM1') RMTJRNRDB('BETA')
   ```

2. On BETA:

   ```
   RMVMQMJRN MQMNAME('QM1') RMTJRNRDB('ALPHA')
   ```

After deleting the journals, continue with the rest of the steps.

Backing up a multi-instance queue manager:

The procedure shows you how to back up queue manager objects on the local server and the queue manager data on the network file server. Adapt the example to back up data for other queue managers.

Before you begin

In this example, the queue manager data associated with the queue manager `QM1` is stored on the IBM i server called GAMMA, using NetServer. See "Creating a multi-instance queue manager using journal mirroring and NetServer" on page 234. IBM MQ is installed on the servers, ALPHA and BETA. The queue manager, `QM1`, is configured on ALPHA and BETA.

About this task

IBM i does not support saving data from a remote directory. Save the queue manager data on a remote file system using the backup procedures local to the file system server. In this task, the network file system is on an IBM i server, GAMMA. The queue manager data is backed up in a save file on GAMMA.

If the network file system was on Windows or Linux, you might store the queue manager data in a compressed file, and then save it. If you have a back-up system, such as Tivoli Storage Manager, use it to back up the queue manager data.

Procedure

1. Create a save file on ALPHA for the queue manager library associated with `QM1`.

   Use the queue manager library name to name the save file.
   ```
   CRTSAVF FILE(QGPL/QMQM1)
   ```
2. Save the queue manager library in the save file on ALPHA.
   ```
   SAVLIB LIB(QMQM1) DEV(*SAVF) SAVF(QGPL/QMQM1)
   ```
3. Create a save file for the queue manager data directory on GAMMA.

   Use the queue manager name to name the save file.
   ```
   CRTSAVF FILE(QGPL/QMDQM1)
   ```
4. Save the copy of the queue manager data from the local directory on GAMMA.
   ```
   SAV DEV('/QSYS.LIB/QGPL.LIB/QMDQM1.FILE') OBJ('/QIBM/Userdata/mqm/qmgrs/QM1')
   ```

Commands to set up multi-instance queue managers:

IBM MQ has commands to simplify configuring journal replication, adding new queue manager instances, and configuring queue managers to use independent ASP.

The journal commands to create and manage local and remote journals are,

ADDMQMJRN
With this command you can create named local and remote journals for a queue manager instance, and configure whether replication is synchronous or asynchronous, what the synchronous timeout is, and if the remote journal is to be activated immediately.

CHGMQMJRN
The command modifies the timeout, status and delivery parameters affecting replica journals.

RMVMQMJRN
Removes named *remote* journals from a queue manager instance.

WRKMQMJRN
Lists the status of local and remote journals for a local queue manager instance.

Add and manage additional queue manager instances using the following commands, which modify the `mqs.ini` file.

ADDMQMINF
The command uses information you extracted from the `mqs.ini` file with DSPMQMINF command to add a new queue manager instance on a different IBM i server.

RMVMQMINF
Remove a queue manager instance. Use this command either to remove an instance of an existing queue manager, or to remove the configuration information for a queue manager that has been deleted from a different server.

The **CRTMQM** command has three parameters to assist configuring a multi-instance queue manager,

MQMDIRP (*DFT| ***directory-prefix*****)**
Use this parameter to select a mount point that is mapped to queue manager data on networked storage.

ASP (*SYSTEM | *ASPDEV | ***auxiliary-storage-pool-number*****)**
Specify `*SYSTEM`, or an *auxiliary-storage-pool-number* to place the queue manager journal on the system or a basic user ASP. Select the `*ASPDEV` option, and also set a device name using the **ASPDEV** parameter, to place the queue manager journal on an independent ASP.

ASPDEV (*ASP | ***device-name*****)**
Specify a *device-name* of a primary or secondary independent ASP device. Selecting `*ASP` has the same result as specifying **ASP** `(*SYSTEM)`.

Performance and disk failover considerations

Use different auxiliary storage pools to improve performance and reliability.

If you use a large number of persistent messages or large messages in your applications, the time spent writing these message to disk becomes a significant factor in the performance of the system.

Ensure that you have sufficient disk activation to cope with this possibility, or consider a separate Auxiliary Storage Pool (ASP) in which to hold your queue manager journal receivers.

You can specify which ASP your queue manager library and journals are stored on when you create your queue manager using the ASP parameter of **CRTMQM**. By default, the queue manager library and journals and IFS data are stored in the system ASP.

ASPs allow isolation of objects on one or more specific disk units. This can also reduce the loss of data because of a disk media failure. In most cases, only the data that is stored on disk units in the affected ASP is lost.

You are recommended to store the queue manager library and journal data in separate user ASPs to that of the root IFS file system to provide failover and reduce disk contention.

For more information, see Backup and recovery.

Using SAVLIB to save IBM MQ libraries

You cannot use `SAVLIB LIB(*ALLUSR)` to save the IBM MQ libraries, because these libraries have names beginning with Q.

You can use `SAVLIB LIB(QM*)` to save all the queue manager libraries, but only if you are using a save device other than *SAVF. For `DEV(*SAVF)`, you must use a SAVLIB command for each and every queue manager library on your system.

Quiescing IBM MQ for IBM i

This section explains how to quiesce (end gracefully) IBM MQ for IBM i

To quiesce IBM MQ for IBM i:

1. Sign on to a new interactive IBM MQ for IBM i session, ensuring that you are not accessing any objects.
2. Ensure that you have:
   - *ALLOBJ authority , or object management authority for the QMQM library
   - Sufficient authority to use the ENDSBS command
3. Advise all users that you are going to stop IBM MQ for IBM i.
4. How you then proceed depends on whether you want to shut down (quiesce) a single queue manager (where others might exist) (see "Shutting down a single queue manager for IBM MQ for IBM i" on page 253) or all the queue managers (see "Shutting down all queue managers for IBM MQ for IBM i" on page 254).

ENDMQM parameter ENDCCTJOB(*YES)

The ENDMQM parameter ENDCCTJOB(*YES) works differently in IBM MQ for IBM i V6.0 and later compared to previous versions.

On previous versions, when you specify ENDCCTJOB(*YES), MQ forcibly terminates your applications for you.

On IBM MQ for IBM i V6.0 or later, when you specify ENDCCTJOB(*YES), your applications are not terminated but are instead disconnected from the queue manager.

If you specify ENDCCTJOB(*YES) and you have applications that are not written to detect that a queue manager is ending, the next time a new MQI call is issued, the call will return with a MQRC_CONNECTION_BROKEN (2009) error.

As an alternative to using ENDCCTJOB(*YES), use the parameter ENDCCTJOB(*NO) and use WRKMQM option 22 (Work with jobs) to manually end any application jobs that will prevent a queue manager restart.

Shutting down a single queue manager for IBM MQ for IBM i

Use this information to understand the three types of shutdown.

In the procedures that follow, we use a sample queue manager name of `QMgr1` and a sample subsystem name of `SUBX`. Replace these names with your own values if necessary.

Planned shutdown

Planned shutdown of a queue manager on IBM i

1. Before shutdown, execute:
   ```
   RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) MQMNAME(QMgr1) DSPJRNDTA(*YES)
   ```
2. To shut down the queue manager, execute:
   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*CNTRLD)
   ```
   If QMgr1 does not end, the channel or applications are probably busy.
3. If you must shut down QMgr1 immediately, execute the following:
   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ENDCCTJOB(*YES) TIMEOUT(15)
   ```

Unplanned shutdown

1. To shut down the queue manager, execute:
   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ```
   If QMgr1 does not end, the channel or applications are probably busy.
2. If you need to shut down QMgr1 immediately, execute the following:
   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ENDCCTJOB(*YES) TIMEOUT(15)
   ```

Shutdown under abnormal conditions

1. To shut down the queue manager, execute:
   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ```
   If QMgr1 does not end, continue with step 3 providing that:
   - QMgr1 is in its own subsystem, or
   - You can end all queue managers that share the same subsystem as QMgr1. Use the unplanned shutdown procedure for all such queue managers.
2. When you have taken all the steps in the procedure for all the queue managers sharing the subsystem (`SUBX` in our examples), execute:
   ```
   ENDSBS SUBX *IMMED
   ```
   If this command fails to complete, shut down all queue managers, using the unplanned shutdown procedure, and perform an IPL on your machine.

   Warning: Do not use `ENDJOBABN` for IBM MQ jobs that fail to end as result of `ENDJOB` or `ENDSBS`, unless you are prepared to perform an IPL on your machine immediately after.
3. Start the subsystem by executing:
   ```
   STRSBS SUBX
   ```
4. Shut down the queue manager immediately, by executing:
   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ENDCCTJOB(*YES) TIMEOUT(10)
   ```
5. Restart the queue manager by executing:
   ```
   STRMQM MQMNAME(QMgr1)
   ```

If this fails, and you:
- Have restarted your machine by performing an IPL, or
- Have only a single queue manager

Tidy up IBM MQ shared memory by executing:

```
ENDMQM MQMNAME(*ALL) OPTION(*IMMED)
ENDCCTJOB(*YES) TIMEOUT(15)
```

before repeating step 5.

If the queue manager restart takes more than a few seconds, IBM MQ adds status messages intermittently to the job log detailing the startup progress.

If you still have problems restarting your queue manager, contact IBM support. Any further action you might take could damage the queue manager, leaving IBM MQ unable to recover.

Shutting down all queue managers for IBM MQ for IBM i

Use this information to understand the three types of shutdown.

The procedures are almost the same as for a single queue manager, but using `*ALL` instead of the queue manager name where possible, and otherwise using a command repeatedly using each queue manager name in turn. Throughout the procedures, we use a sample queue manager name of `QMgr1` and a sample subsystem name of `SUBX`. Replace these with your own.

Planned shutdown

1. One hour before shutdown, execute:

   ```
   RCDMQMIMG OBJ(*ALL) OBJTYPE(*ALL) MQMNAME(QMgr1) DSPJRNDTA(*YES)
   ```

   Repeat this for every queue manager that you want to shut down.
2. To shut down the queue manager, execute:

   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*CNTRLD)
   ```

   Repeat this for every queue manager that you want to shut down; separate commands can run in parallel.

   If any queue manager does not end within a reasonable time (for example 10 minutes), proceed to step 3.
3. To shut down all queue managers immediately, execute the following:

   ```
   ENDMQM MQMNAME(*ALL) OPTION(*IMMED)
   ENDCCTJOB(*YES) TIMEOUT(15)
   ```

Unplanned shutdown

1. To shut down a queue manager, execute:

   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ```

   Repeat this for every queue manager that you want to shut down; separate commands can run in parallel.

   If queue managers do not end, the channel or applications are probably busy.
2. If you need to shut down the queue managers immediately, execute the following:

   ```
   ENDMQM MQMNAME(*ALL) OPTION(*IMMED)
   ENDCCTJOB(*YES) TIMEOUT(15)
   ```

Shutdown under abnormal conditions

1. To shut down the queue managers, execute:

   ```
   ENDMQM MQMNAME(QMgr1) OPTION(*IMMED)
   ```

Repeat this for every queue manager that you want to shut down; separate commands can run in parallel.

2. End the subsystems (`SUBX` in our examples), by executing:

   ```
   ENDSBS SUBX *IMMED
   ```

   Repeat this for every subsystem that you want to shut down; separate commands can run in parallel.

   If this command fails to complete, perform an IPL on your system.

   Warning: Do not use `ENDJOBABN` for jobs that fail to end as result of `ENDJOB` or `ENDSBS`, unless you are prepared to perform an IPL on your system immediately after.

3. Start the subsystems by executing:

   ```
   STRSBS SUBX
   ```

   Repeat this for every subsystem that you want to start.

4. Shut the queue managers down immediately, by executing:

   ```
   ENDMQM MQMNAME(*ALL) OPTION(*IMMED)
   ENDCCTJOB(*YES) TIMEOUT(15)
   ```

5. Restart the queue managers by executing:

   ```
   STRMQM MQMNAME(QMgr1)
   ```

   Repeat this for every queue manager that you want to start.

   If any queue manager restart takes more than a few seconds IBM MQ will show status messages intermittently detailing the startup progress.

   If you still have problems restarting any queue manager, contact IBM support. Any further action you might take could damage the queue managers, leaving MQSeries or IBM MQ unable to recover.

Administering IBM MQ for z/OS

z/OS

Administering queue managers and associated resources includes the tasks that you perform frequently to activate and manage those resources. Choose the method you prefer to administer your queue managers and associated resources.

IBM MQ for z/OS can be controlled and managed by a set of utilities and programs provided with the product. You can use the IBM MQ Script (MQSC) commands or Programmable Command Formats (PCFs) to administer IBM MQ for z/OS. For information about using commands for IBM MQ for z/OS, see "Issuing commands to IBM MQ for z/OS" on page 256.

IBM MQ for z/OS also provides a set of utility programs to help you with system administration. For information about the different utility programs and how to use them, see "The IBM MQ for z/OS utilities" on page 264.

For details of how to administer IBM MQ for z/OS and the different administrative tasks you might have to undertake, see the following links:

Issuing commands to IBM MQ for z/OS

You can use IBM MQ script commands (MQSC) in batch or interactive mode to control a queue manager.

IBM MQ for z/OS supports MQSC commands, which can be issued from the following sources:
- The z/OS console or equivalent (such as SDSF/TSO).
- The initialization input data sets.
- The supplied batch utility, CSQUTIL, processing a list of commands in a sequential data set.
- A suitably authorized application, by sending a command as a message to the command input queue. The application can be any of the following:
  - A batch region program
  - A CICS application
  - An IMS™ application
  - A TSO application
  - An application program or utility on another IBM MQ system

Table 12 on page 260 summarizes the MQSC commands and the sources from which they can be issued.

Much of the functionality of these commands is available in a convenient way from the IBM MQ for z/OS operations and controls panels.

Changes made to the resource definitions of a queue manager using the commands (directly or indirectly) are preserved across restarts of the IBM MQ subsystem.

IBM MQ for z/OS also supports Programmable Command Format (PCF) commands. These simplify the creation of applications for the administration of IBM MQ. MQSC commands are in human-readable text form, whereas PCF enables applications to create requests and read the replies without having to parse text strings. Like MQSC commands, applications issue PCF commands by sending them as messages to the command input queue. For more information about using PCF commands and for details of the commands, see the Programmable command formats reference documentation.

Private and global definitions

When you define an object on IBM MQ for z/OS, you can choose whether you want to share that definition with other queue managers (a *global* definition), or whether the object definition is to be used by one queue manager only (a *private* definition). This is called the object *disposition*.

Global definition

If your queue manager belongs to a queue-sharing group, you can choose to share any object definitions you make with the other members of the group. This means that you have to define an object once only, reducing the total number of definitions required for the whole system.

Global object definitions are held in a *shared repository* (a Db2 shared database), and are available to all the queue managers in the queue-sharing group. These objects have a disposition of GROUP.

Private definition

If you want to create an object definition that is required by one queue manager only, or if your queue manager is not a member of a queue-sharing group, you can create object definitions that are not shared with other members of a queue-sharing group.

Private object definitions are held on page set zero of the defining queue manager. These objects have a disposition of QMGR.

You can create private definitions for all types of IBM MQ objects except CF structures (that is, channels, namelists, process definitions, queues, queue managers, storage class definitions, and authentication information objects), and global definitions for all types of objects except queue managers.

IBM MQ automatically copies the definition of a group object to page set zero of each queue manager that uses it. You can alter the copy of the definition temporarily if you want, and IBM MQ allows you to refresh the page set copies from the repository copy if required.

IBM MQ always tries to refresh the page set copies from the repository copy on start up (for channel commands, this is done when the channel initiator restarts), or if the group object is changed.

Note: The copy of the definition is refreshed from the definition of the group, only if the definition of the group has changed after you created the copy of the definition.

This ensures that the page set copies reflect the version on the repository, including any changes that were made when the queue manager was inactive. The copies are refreshed by generating DEFINE REPLACE commands, therefore there are circumstances under which the refresh is not performed, for example:

- If a copy of the queue is open, a refresh that changes the usage of the queue fails.
- If a copy of a queue has messages on it, a refresh that deletes that queue fails.
- If a copy of a queue would require ALTER with FORCE to change it.

In these circumstances, the refresh is not performed on that copy, but is performed on the copies on all other queue managers.

If the queue manager is shut down and then restarted stand-alone, any local copies of objects are deleted, unless for example, the queue has associated messages.

There is a third object disposition that applies to local queues only. This allows you to create shared queues. The definition for a shared queue is held on the shared repository and is available to all the queue managers in the queue-sharing group. In addition, the messages on a shared queue are also available to all the queue managers in the queue sharing group. This is described in Shared queues and queue-sharing groups. Shared queues have an object disposition of SHARED.

The following table summarizes the effect of the object disposition options for queue managers started stand-alone, and as a member of a queue-sharing group.

Disposition	Stand-alone queue manager	Member of a queue-sharing group
QMGR	Object definition held on page set zero.	Object definition held on page set zero.
GROUP	Not allowed.	Object definition held in the shared repository. Local copy held on page set zero of each queue manager in the group.
SHARED	Not allowed.	Queue definition held in the shared repository. Messages available to any queue manager in the group.

Manipulating global definitions

If you want to change the definition of an object that is held in the shared repository, you need to specify whether you want to change the version on the repository, or the local copy on page set zero. Use the object disposition as part of the command to do this.

Directing commands to different queue managers

You can use the *command scope* to control on which queue manager the command runs.

You can choose to execute a command on the queue manager where it is entered, or on a different queue manager in the queue-sharing group. You can also choose to issue a particular command in parallel on all the queue managers in a queue-sharing group. This is possible for both MQSC commands and PCF commands.

This is determined by the *command scope*. The command scope is used with the object disposition to determine which version of an object you want to work with.

For example, you might want to alter some of the attributes of an object, the definition of which is held in the shared repository.

- You might want to change the version on one queue manager only, and not make any changes to the version on the repository or those in use by other queue managers.
- You might want to change the version in the shared repository for future users, but leave existing copies unchanged.
- You might want to change the version in the shared repository, but also want your changes to be reflected immediately on all the queue managers in the queue-sharing group that hold a copy of the object on their page set zero.

Use the command scope to specify whether the command is executed on this queue manager, another queue manager, or all queue managers. Use the object disposition to specify whether the object you are manipulating is in the shared repository (a group object), or is a local copy on page set zero (a queue manager object).

You do not have to specify the command scope and object disposition to work with a shared queue because every queue manager in the queue-sharing group handles the shared queue as a single queue.

Command summary

Use this topic as a reference of the main MQSC and PCF commands.

Table 11 summarizes the MQSC and PCF commands that are available on IBM MQ for z/OS to alter, define, delete and display IBM MQ objects.

Table 11. Summary of the main MQSC and PCF commands by object type

MQSC command	**ALTER**	**DEFINE**	**DISPLAY**	**DELETE**
PCF command	**Change**	**Create/Copy**	**Inquire**	**Delete**
AUTHINFO	X	X	X	X
CFSTATUS			X	
CFSTRUCT	X	X	X	X

QSTATUS			X	
STGCLASS	X	X	X	X

Key to table symbols:

- M = MQSC only
- P = PCF only
- X = both

There are many other MQSC and PCF commands which allow you to manage other IBM MQ resources, and carry out other actions in addition to those summarized in Table 11.

Table 12 on page 260 shows every MQSC command, and where each command can be issued from:

- CSQINP1 initialization input data set
- CSQINP2 initialization input data set
- z/OS console (or equivalent)
- SYSTEM.COMMAND.INPUT queue and command server (from applications, CSQUTIL, or the CSQINPX initialization input data set)

In MQSC commands, each command description identifies the sources from which that command can be run.

Initialization commands

Initialization commands can be used to control the queue manager startup.

Commands in the initialization input data sets are processed when IBM MQ is initialized on queue manager startup. Three types of command can be issued from the initialization input data sets:

- Commands to define IBM MQ entities that cannot be defined elsewhere, for example DEFINE BUFFPOOL.

  These commands must reside in the data set identified by the DD name CSQINP1. They are processed before the restart phase of initialization. They cannot be issued through the console, operations and control panels, or an application program. The responses to these commands are written to the sequential data set that you refer to in the CSQOUT1 statement of the started task procedure.
- Commands to define IBM MQ objects that are recoverable after restart. These definitions must be specified in the data set identified by the DD name CSQINP2. They are stored in page set zero. CSQINP2 is processed after the restart phase of initialization. The responses to these commands are written to the sequential data set that you refer to in the CSQOUT2 statement of the started task procedure.
- Commands to manipulate IBM MQ objects. These commands must also be specified in the data set identified by the DD name CSQINP2. For example, the IBM MQ-supplied sample contains an ALTER QMGR command to specify a dead-letter queue for the subsystem. The response to these commands is written to the CSQOUT2 output data set.

Note: If IBM MQ objects are defined in CSQINP2, IBM MQ attempts to redefine them each time the queue manager is started. If the objects already exist, the attempt to define them fails. If you need to define your objects in CSQINP2, you can avoid this problem by using the REPLACE parameter of the DEFINE commands, however, this overrides any changes that were made during the previous run of the queue manager.

Sample initialization data set members are supplied with IBM MQ for z/OS. They are described in Sample definitions supplied with IBM MQ.

Initialization commands for distributed queuing

You can also use the CSQINP2 initialization data set for the START CHINIT command. If you need a series of other commands to define your distributed queuing environment (for example, starting listeners), IBM MQ provides a third initialization input data set, called CSQINPX, that is processed as part of the channel initiator started task procedure.

The MQSC commands contained in the data set are executed at the end of channel initiator initialization, and output is written to the data set specified by the CSQOUTX DD statement. You might use the CSQINPX initialization data set to start listeners for example.

A sample channel initiator initialization data set member is supplied with IBM MQ for z/OS. It is described in Sample definitions supplied with IBM MQ.

Initialization commands for publish/Subscribe

If you need a series of commands to define your publish/subscribe environment (for example, when defining subscriptions), IBM MQ provides a fourth initialization input data set, called CSQINPT.

The MQSC commands contained in the data set are executed at the end of publish/subscribe initialization, and output is written to the data set specified by the CSQOUTT DD statement. You might use the CSQINPT initialization data set to define subscriptions for example.

A sample publish/subscribe initialization data set member is supplied with IBM MQ for z/OS. It is described in Sample definitions supplied with IBM MQ.

The IBM MQ for z/OS utilities

IBM MQ for z/OS provides a set of utility programs that you can use to help with system administration.

IBM MQ for z/OS supplies a set of utility programs to help you perform various administrative tasks, including the following:
- Manage message security policies.
- Perform backup, restoration, and reorganization tasks.
- Issue commands and process object definitions.
- Generate data-conversion exits.
- Modify the bootstrap data set.
- List information about the logs.
- Print the logs.
- Set up Db2 tables and other Db2 utilities.
- Process messages on the dead-letter queue.

The message security policy utility

The message security policy utility (CSQ0UTIL) runs as a stand-alone utility to manage message security policies. See The message security policy utility (CSQ0UTIL) for more information.

The CSQUTIL utility

This is a utility program provided to help you with backup, restore and reorganize tasks. See The CSQUTIL utility for more information.

The data conversion exit utility

The IBM MQ for z/OS data conversion exit utility (`CSQUCVX`) runs as a stand-alone utility to create data conversion exit routines.

The change log inventory utility

The IBM MQ for z/OS change log inventory utility program (`CSQJU003`) runs as a stand-alone utility to change the bootstrap data set (BSDS). You can use the utility to perform the following functions:
- Add or delete active or archive log data sets.
- Supply passwords for archive logs.

The print log map utility

The IBM MQ for z/OS print log map utility program (`CSQJU004`) runs as a stand-alone utility to list the following information:
- Log data set name and log RBA association for both copies of all active and archive log data sets. If dual logging is not active, there is only one copy of the data sets.
- Active log data sets available for new log data.
- Contents of the queue of checkpoint records in the bootstrap data set (BSDS).
- Contents of the archive log command history record.
- System and utility time stamps.

The log print utility

The log print utility program (`CSQ1LOGP`) is run as a stand-alone utility. You can run the utility specifying:

- A bootstrap data set (BSDS)
- Active logs (with no BSDS)
- Archive logs (with no BSDS)

The queue-sharing group utility

The queue-sharing group utility program (`CSQ5PQSG`) runs as a stand-alone utility to set up Db2 tables and perform other Db2 tasks required for queue-sharing groups.

The active log preformat utility

The active log preformat utility (`CSQJUFMT`) formats active log data sets before they are used by a queue manager. If the active log data sets are preformatted by the utility, log write performance is improved on the queue manager's first pass through the active logs.

The dead-letter queue handler utility

The dead-letter queue handler utility program (`CSQUDLQH`) runs as a stand-alone utility. It checks messages that are on the dead-letter queue and processes them according to a set of rules that you supply to the utility.

The CSQUTIL utility

The CSQUTIL utility program is provided with IBM MQ for z/OS to help you perform backup, restoration, and reorganization tasks, and to issue commands and process object definitions.

For more information about the CSQUTIL utility program, see IBM MQ utility program (CSQUTIL). By using this utility program, you can invoke the following functions:

COMMAND
: To issue MQSC commands, to record object definitions, and to make client-channel definition files.

COPY
: To read the contents of a named IBM MQ for z/OS message queue or the contents of all the queues of a named page set, and put them into a sequential file and retain the original queue.

COPYPAGE
: To copy whole page sets to larger page sets.

EMPTY
: To delete the contents of a named IBM MQ for z/OS message queue or the contents of all the queues of a named page set, retaining the definitions of the queues.

FORMAT
: To format IBM MQ for z/OS page sets.

LOAD
: To restore the contents of a named IBM MQ for z/OS message queue or the contents of all the queues of a named page set from a sequential file created by the COPY function.

PAGEINFO
: To extract page set information from one or more page sets.

RESETPAGE
: To copy whole page sets to other page set data sets and reset the log information in the copy.

SCOPY
To copy the contents of a queue to a data set while the queue manager is offline.

SDEFS
To produce a set of define commands for objects while the queue manager is offline.

SLOAD
To restore messages from the destination data set of an earlier COPY or SCOPY operation. SLOAD processes a single queue.

SWITCH
To switch or query the transmission queue associated with cluster-sender channels.

XPARM
To convert a channel initiator parameter load module into queue manager attributes (for migration purposes).

Operating IBM MQ for z/OS

Use these basic procedures to operate IBM MQ for z/OS.

You can also perform the operations described in this section using the IBM MQ Explorer, which is distributed with IBM MQ for Windows, IBM MQ for Linux (x86 and x86-64 platforms) and SupportPac MS0T. For more information, see "Administration using the MQ Explorer" on page 56 and IBM Support & downloads.

This section contains information about the following topics:

Issuing queue manager commands

You can issue IBM MQ control commands from a z/OS console or with the utility program CSQUTIL. Commands can use command prefix string (CPF) to indicate which IBM MQ subsystem processes the command.

You can control most of the operational environment of IBM MQ using the IBM MQ commands. IBM MQ for z/OS supports both the MQSC and PCF types of these commands. This topic describes how to specify attributes using MQSC commands, and so it refers to those commands and attributes using their MQSC command names, rather than their PCF names. For details of the syntax of the MQSC commands, see The MQSC commands. For details of the syntax of the PCF commands, see "Using Programmable Command Formats" on page 7. If you are a suitably authorized user, you can issue IBM MQ commands from:

- The initialization input data sets (described in "Initialization commands" on page 263).
- A z/OS console, or equivalent, such as SDSF
- The z/OS master get command routine, MGCRE (SVC 34)
- The IBM MQ utility, CSQUTIL (described in IBM MQ utility program.)
- A user application, which can be:
  - A CICS program
  - A TSO program
  - A z/OS batch program
  - An IMS program

  See "Writing programs to administer IBM MQ" on page 287 for information about this.

Much of the functionality of these commands is provided in a convenient way by the operations and control panels, accessible from TSO and ISPF, and described in "Introducing the operations and control panels" on page 272.

For further information, see

- "Issuing commands from a z/OS console or its equivalent"
  - Command prefix strings
  - Using the z/OS console to issue commands
  - Command responses
- Issuing commands from the utility program CSQUTIL

Issuing commands from a z/OS console or its equivalent

You can issue all IBM MQ commands from a z/OS console or its equivalent. You can also issue IBM MQ commands from anywhere where you can issue z/OS commands, such as SDSF or by a program using the MGCRE macro.

The maximum amount of data that can be displayed as a result of a command typed in at the console is 32 KB.

Note:

1. You cannot issue IBM MQ commands using the IMS/SSR command format from an IMS terminal. This function is not supported by the IMS adapter.
2. The input field provided by SDSF might not be long enough for some commands, particularly those commands for channels.

Command prefix strings

Each IBM MQ command must be prefixed with a command prefix string (CPF), as shown in Figure 39.

Because more than one IBM MQ subsystem can run under z/OS, the CPF is used to indicate which IBM MQ subsystem processes the command. For example, to start the queue manager for a subsystem called CSQ1, where CPF is ' `+CSQ1` ', you issue the command `+CSQ1` START QMGR from the operator console. This CPF must be defined in the subsystem name table (for the subsystem CSQ1). This is described in Defining command prefix strings (CPFs). In the examples, the string ' `+CSQ1` ' is used as the command prefix.

Using the z/OS console to issue commands

You can type simple commands from the z/OS console, for example, the DISPLAY command in Figure 39. However, for complex commands or for sets of commands that you issue frequently, the other methods of issuing commands are better.

```
+CSQ1 DISPLAY QUEUE(TRANSMIT.QUEUE.PROD) TYPE(QLOCAL)
```

Figure 39. Issuing a DISPLAY command from the z/OS console

Command responses

Direct responses to commands are sent to the console that issued the command. IBM MQ supports the *Extended Console Support* (EMCS) function available in z/OS, and therefore consoles with 4 byte IDs can be used. Additionally, all commands except START QMGR and STOP QMGR support the use of Command and Response Tokens (CARTs) when the command is issued by a program using the MGCRE macro.

Issuing commands from the utility program CSQUTIL

You can issue commands from a sequential data set using the COMMAND function of the utility program CSQUTIL. This utility transfers the commands, as messages, to the *system-command input queue* and waits for the response, which is printed together with the original commands in SYSPRINT. For details of this, see IBM MQ utility program.

Starting and stopping a queue manager:

Use this topic as an introduction to stopping and starting a queue manager.

This section describes how to start and stop a queue manager. It contains information about the following topics:
- "Before you start IBM MQ"
- "Starting a queue manager"
- "Stopping a queue manager" on page 270

Starting and stopping a queue manager is relatively straightforward. When a queue manager stops under normal conditions, its last action is to take a termination checkpoint. This checkpoint, and the logs, give the queue manager the information it needs to restart.

This section contains information about the START and STOP commands, and contains a brief overview of start-up after an abnormal termination has occurred.

Before you start IBM MQ

After you have installed IBM MQ, it is defined as a formal z/OS subsystem. This message appears during any initial program load (IPL) of z/OS:

```
CSQ3110I +CSQ1 CSQ3UR00 - SUBSYSTEM ssnm INITIALIZATION COMPLETE
```

where *ssnm* is the IBM MQ subsystem name.

From now on, you can start the queue manager for that subsystem *from any z/OS console that has been authorized to issue system control commands* ; that is, a z/OS SYS command group. You must issue the START command from the authorized console, you cannot issue it through JES or TSO.

If you are using queue-sharing groups, you must start RRS first, and then Db2, before you start the queue manager.

Starting a queue manager

You start a queue manager by issuing a START QMGR command. However, you cannot successfully use the START command unless you have appropriate authority. See the Setting up security on z/OS for information about IBM MQ security. Figure 40 shows examples of the START command. (Remember that you must prefix an IBM MQ command with a command prefix string (CPF).)

```
+CSQ1  START QMGR

+CSQ1  START QMGR PARM(NEWLOG)
```

Figure 40. Starting the queue manager from a z/OS console. The second example specifies a system parameter module name.

See START QMGR for information about the syntax of the START QMGR command.

You cannot run the queue manager as a batch job or start it using a z/OS command START. These methods are likely to start an address space for IBM MQ that then ends abnormally. Nor can you start a queue manager from the CSQUTIL utility program or a similar user application.

You can, however, start a queue manager from an APF-authorized program by passing a START QMGR command to the z/OS MGCRE (SVC 34) service.

If you are using queue-sharing groups, the associated Db2 systems and RRS must be active when you start the queue manager.

Start options

When you start a queue manager, a system parameter module is loaded. You can specify the name of the system parameter module in one of two ways:

- With the PARM parameter of the /cpf START QMGR command, for example
  ```
  /cpf START QMGR PARM(CSQ1ZPRM)
  ```
- With a parameter in the startup procedure, for example, code the JCL EXEC statement as
  ```
  //MQM  EXEC PGM=CSQYASCP,PARM='ZPARM(CSQ1ZPRM)'
  ```

A system parameter module provides information specified when the queue manager was customized.

You can also use the ENVPARM option to substitute one or more parameters in the JCL procedure for the queue manager.

For example, you can update your queue manager startup procedure, so that the DDname CSQINP2 is a variable. This means that you can change the CSQINP2 DDname without changing the startup procedure. This is useful for implementing changes, providing backouts for operators, and queue manager operations.

Suppose your start-up procedure for queue manager CSQ1 looked like Figure 41.

```
//CSQ1MSTR PROC INP2=NORM
//MQMESA  EXEC PGM=CSQYASCP
//STEPLIB DD  DISP=SHR,DSN=thlqual.SCSQANLE
//     DD  DISP=SHR,DSN=thlqual.SCSQAUTH
//     DD  DISP=SHR,DSN=db2qual.SDSNLOAD
//BSDS1  DD  DISP=SHR,DSN=myqual.BSDS01
//BSDS2  DD  DISP=SHR,DSN=myqual.BSDS02
//CSQP0000 DD  DISP=SHR,DSN=myqual.PSID00
//CSQP0001 DD  DISP=SHR,DSN=myqual.PSID01
//CSQP0002 DD  DISP=SHR,DSN=myqual.PSID02
//CSQP0003 DD  DISP=SHR,DSN=myqual.PSID03
//CSQINP1 DD  DISP=SHR,DSN=myqual.CSQINP(CSQ1INP1)
//CSQINP2 DD  DISP=SHR,DSN=myqual.CSQINP(CSQ1&INP2.)
//CSQOUT1 DD  SYSOUT=*
//CSQOUT2 DD  SYSOUT=*
```

Figure 41. Sample start-up procedure

If you then start your queue manager with the command:

```
+CSQ1  START QMGR
```

the CSQINP2 used is a member called CSQ1NORM.

However, suppose you are putting a new suite of programs into production so that the next time you start queue manager CSQ1, the CSQINP2 definitions are to be taken from member CSQ1NEW. To do this, you would start the queue manager with this command:

```
+CSQ1  START QMGR ENVPARM('INP2=NEW')
```

and CSQ1NEW would be used instead of CSQ1NORM. Note: z/OS limits the `KEYWORD=value` specifications for symbolic parameters (as in `INP2=NEW`) to 255 characters.

Starting after an abnormal termination

IBM MQ automatically detects whether restart follows a normal shutdown or an abnormal termination.

Starting a queue manager after it ends abnormally is different from starting it after the STOP QMGR command has been issued. After STOP QMGR, the system finishes its work in an orderly way and takes a termination checkpoint before stopping. When you restart the queue manager, it uses information from the system checkpoint and recovery log to determine the system status at shutdown.

However, if the queue manager ends abnormally, it terminates without being able to finish its work or take a termination checkpoint. When you restart a queue manager after an abend, it refreshes its knowledge of its status at termination using information in the log, and notifies you of the status of various tasks. Normally, the restart process resolves all inconsistent states. But, in some cases, you must take specific steps to resolve inconsistencies.

User messages on start-up

When you start a queue manager successfully, the queue manager produces a set of startup messages.

Stopping a queue manager

Before stopping a queue manager, all IBM MQ-related write-to-operator-with-reply (WTOR) messages must receive replies, for example, getting log requests. Each command in Figure 42 terminates a running queue manager.

```
+CSQ1  STOP QMGR

+CSQ1  STOP QMGR MODE(QUIESCE)

+CSQ1  STOP QMGR MODE(FORCE)

+CSQ1  STOP QMGR MODE(RESTART)
```

Figure 42. Stopping a queue manager

The command STOP QMGR defaults to STOP QMGR MODE(QUIESCE).

In QUIESCE mode, IBM MQ does not allow any new connection threads to be created, but allows existing threads to continue; it terminates only when all threads have ended. Applications can request to be notified in the event of the queue manager quiescing. Therefore, use the QUIESCE mode where possible so that applications that have requested notification have the opportunity to disconnect. See What happens during termination for details.

If the queue manager does not terminate in a reasonable time in response to a STOP QMGR MODE(QUIESCE) command, use the DISPLAY CONN command to determine whether any connection threads exist, and take the necessary steps to terminate the associated applications. If there are no threads, issue a STOP QMGR MODE(FORCE) command.

The STOP QMGR MODE(QUIESCE) and STOP QMGR MODE(FORCE) commands deregister IBM MQ from the MVS Automatic Restart Manager (ARM), preventing ARM from restarting the queue manager automatically. The STOP QMGR MODE(RESTART) command works in the same way as the STOP QMGR MODE(FORCE) command, except that it does not deregister IBM MQ from ARM. This means that the queue manager is eligible for immediate automatic restart.

If the IBM MQ subsystem is not registered with ARM, the STOP QMGR MODE(RESTART) command is rejected and the following message is sent to the z/OS console:

```
CSQY205I ARM element arm-element is not registered
```

If this message is not issued, the queue manager is restarted automatically. For more information about ARM, see "Using the z/OS Automatic Restart Manager (ARM)" on page 349.

Only cancel the queue manager address space if STOP QMGR MODE(FORCE) does not terminate the queue manager.

If a queue manager is stopped by either canceling the address space or by using the command STOP QMGR MODE(FORCE), consistency is maintained with connected CICS or IMS systems. Resynchronization of resources is started when a queue manager restarts and is completed when the connection to the CICS or IMS system is established.

Note: When you stop your queue manager, you might find message IEF352I is issued. z/OS issues this message if it detects that failing to mark the address space as unusable would lead to an integrity exposure. You can ignore this message.

Stop messages

After issuing a STOP QMGR command, you get the messages CSQY009I and CSQY002I, for example:

```
CSQY009I +CSQ1 ' STOP QMGR' COMMAND ACCEPTED FROM
USER(userid), STOP MODE(FORCE)
CSQY002I +CSQ1 QUEUE MANAGER STOPPING
```

Where `userid` is the user ID that issued the STOP QMGR command, and the MODE parameter depends on that specified in the command.

When the STOP command has completed successfully, the following messages are displayed on the z/OS console:

```
CSQ9022I +CSQ1 CSQYASCP ' STOP QMGR' NORMAL COMPLETION
CSQ3104I +CSQ1 CSQ3EC0X - TERMINATION COMPLETE
```

If you are using ARM, and you did not specify MODE(RESTART), the following message is also displayed:

```
CSQY204I +CSQ1 ARM DEREGISTER for element arm-element type
arm-element-type successful
```

You cannot restart the queue manager until the following message has been displayed:

```
CSQ3100I +CSQ1 CSQ3EC0X - SUBSYSTEM ssnm READY FOR START COMMAND
```

Introducing the operations and control panels

You can use the IBM MQ operations and control panels to perform administration tasks on IBM MQ objects. Use this topic as an introduction to the commands, and control panels.

You use these panels for defining, displaying, altering, or deleting IBM MQ objects. Use the panels for day-to-day administration and for making small changes to objects. If you are setting up or changing many objects, use the COMMAND function of the CSQUTIL utility program.

The operations and control panels support the controls for the channel initiator (for example, to start a channel or a TCP/IP listener), for clustering, and for security. They also enable you to display information about threads and page set usage.

The panels work by sending MQSC type IBM MQ commands to a queue manager, through the system command input queue.

Note:

1. The z/OS IBM MQ operations and controls panels (CSQOREXX) might not support all new function and parameters added from version 7 onwards. For example, there are no panels for the direct manipulation of topic objects or subscriptions.

   Using one of the following supported mechanisms allows you to administer publish/subscribe definitions and other system controls that are not directly available from other panels:

   a. IBM MQ Explorer
   b. z/OS console
   c. Programmable Command Format (PCF) messages
   d. COMMAND function of CSQUTIL

   Note that the generic **Command** action in the CSQOREXX panels allows you to issue any valid MQSC command, including SMDS related commands. You can use all the commands that the COMMAND function of CSQUTIL issues.
2. You cannot issue the IBM MQ commands directly from the command line in the panels.
3. To use the operations and control panels, you must have the correct security authorization; this is described in the User IDs for command security and command resource security.
4. You cannot provide a user ID and password using CSQUTIL, or the CSQOREXX panels. Instead, if you user ID has UPDATE authority to the BATCH profile in MQCONN, you can bypass the **CHCKLOCL**(*REQUIRED* setting. See Using **CHCKLOCL** on locally bound applications for more information.

Invocation and rules for the operations and control panels:

You can control IBM MQ and issue control commands through the ISPF panels.

If the ISPF/PDF primary options menu has been updated for IBM MQ, you can access the IBM MQ operations and control panels from that menu. For details about updating the menu, see the Task 20: Set up the operations and control panels.

You can access the IBM MQ operations and control panels from the TSO command processor panel (typically option 6 on the ISPF/PDF primary options menu). The name of the exec that you run to do this is CSQOREXX. It has two parameters; `thlqual` is the high-level qualifier for the IBM MQ libraries to be used, and `langletter` is the letter identifying the national language libraries to be used (for example, E for U.S. English). The parameters can be omitted if the IBM MQ libraries are permanently installed in your ISPF setup. Alternatively, you can issue CSQOREXX from the TSO command line.

These panels are designed to be used by operators and administrators with a minimum of formal training. Read these instructions with the panels running and try out the different tasks suggested.

Note: While using the panels, temporary dynamic queues with names of the form SYSTEM.CSQOREXX.* are created.

Rules for the operations and control panels

See Rules for naming IBM MQ objects about the general rules for IBM MQ character strings and names. However, there are some rules that apply only to the operations and control panels:

- Do not enclose strings, for example descriptions, in single or double quotation marks.
- If you include an apostrophe or quotation mark in a text field, you do not have to repeat it or add an escape character. The characters are saved exactly as you type them; for example:

  ```
  This is Maria's queue
  ```

  The panel processor doubles them for you to pass them to IBM MQ. However, if it has to truncate your data to do this, it does so.
- You can use uppercase or lowercase characters in most fields, and they are folded to uppercase characters when you press Enter. The exceptions are:
  - Storage class names and coupling facility structure names, which must start with uppercase A through Z and be followed by uppercase A through Z or numeric characters.
  - Certain fields that are not translated. These include:
    - Application ID
    - Description
    - Environment data
    - Object names (but if you use a lowercase object name, you might not be able to enter it at a z/OS console)
    - Remote system name
    - Trigger data
    - User data
- In names, leading blanks and leading underscores are ignored. Therefore, you cannot have object names beginning with blanks or underscores.
- Underscores are used to show the extent of blank fields. When you press Enter, trailing underscores are replaced by blanks.

- Many description and text fields are presented in multiple parts, each part being handled by IBM MQ independently. This means that trailing blanks *are retained* and the text is not contiguous.

Blank fields

When you specify the **Define** action for an IBM MQ object, each field on the define panel contains a value. See the general help (extended help) for the display panels for information about where IBM MQ gets the values. If you type over a field with blanks, and blanks are not allowed, IBM MQ puts the installation default value in the field or prompts you to enter the required value.

When you specify the **Alter** action for an IBM MQ object, each field on the alter panel contains the current value for that field. If you type over a field with blanks, and blanks are not allowed, the value of that field is left unchanged.

Objects and actions:

The operations and control panels offer you many different types of object and a number of actions that you can perform on them.

The actions are listed on the initial panel and enable you to manipulate the objects and display information about them. These objects include all the IBM MQ objects, together with some extra ones. The objects fall into the following categories.
- Queues, processes, authentication information objects, namelists, storage classes and CF structures
- Channels
- Cluster objects
- Queue manager and security
- Connections
- System

Refer to Actions for a cross reference table of the actions which can be taken with the IBM MQ objects.

Queues, processes, authentication information objects, namelists, storage classes and CF structures

These are the basic IBM MQ objects. There can be many of each type. They can be listed, listed with filter, defined, and deleted, and have attributes that can be displayed and altered, using the LIST or DISPLAY, LIST with FILTER, DEFINE LIKE, MANAGE, and ALTER actions. (Objects are deleted using the MANAGE action.)

This category consists of the following objects:

QLOCAL	Local queue
QREMOTE	Remote queue
QALIAS	Alias queue for indirect reference to a queue
QMODEL	Model queue for defining queues dynamically
QUEUE	Any type of queue
QSTATUS	Status of a local queue
PROCESS	Information about an application to be started when a trigger event occurs
AUTHINFO	Authentication information: definitions required to perform Certificate Revocation List (CRL) checking using LDAP servers
NAMELIST	List of names, such as queues or clusters
STGCLASS	Storage class
CFSTRUCT	coupling facility (CF) structure
CFSTATUS	Status of a CF structure

Channels

Channels are used for distributed queuing. There can be many of each type, and they can be listed, listed with filter, defined, deleted, displayed, and altered. They also have other functions available using the START, STOP and PERFORM actions. PERFORM provides reset, ping, and resolve channel functions.

This category consists of the following objects:

CHANNEL	Any type of channel
SENDER	Sender channel
SERVER	Server channel
RECEIVER	Receiver channel
REQUESTER	Requester channel
CLUSRCVR	Cluster-receiver channel
CLUSSDR	Cluster-sender channel
SVRCONN	Server-connection channel
CLNTCONN	Client-connection channel
CHSTATUS	Status of a channel connection

Cluster objects

Cluster objects are created automatically for queues and channels that belong to a cluster. The base queue and channel definitions can be on another queue manager. There can be many of each type, and names can be duplicated. They can be listed, listed with filter, and displayed. PERFORM, START, and STOP are also available through the LIST actions.

This category consists of the following objects:

CLUSQ	Cluster queue, created for a queue that belongs to a cluster
CLUSCHL	Cluster channel, created for a channel that belongs to a cluster
CLUSQMGR	Cluster queue manager, the same as a cluster channel but identified by its queue manager name

Cluster channels and cluster queue managers do have the PERFORM, START and STOP actions, but only indirectly through the DISPLAY action.

Queue manager and security

Queue manager and security objects have a single instance. They can be listed, and have attributes that can be displayed and altered (using the LIST or DISPLAY, and ALTER actions), and have other functions available using the PERFORM action.

This category consists of the following objects:

MANAGER	Queue manager: the PERFORM action provides suspend and resume cluster functions
SECURITY	Security functions: the PERFORM action provides refresh and reverify functions

Connection

Connections can be listed, listed with filter and displayed.

This category consists only of the connection object, CONNECT.

System

A collection of other functions. This category consists of the following objects:

SYSTEM	System functions
CONTROL	Synonym for SYSTEM

The functions available are:

LIST or DISPLAY	Display queue-sharing group, distributed queuing, page set, or data set usage information.
PERFORM	Refresh or reset clustering
START	Start the channel initiator or listeners
STOP	Stop the channel initiator or listeners

Actions

The actions that you can perform for each type of object are shown in the following table:

Table 13. Valid operations and control panel actions for IBM MQ objects

Object	Alter	Define like	Manage (1)	List or Display	List with Filter	Perform	Start	Stop
AUTHINFO	X	X	X	X	X			
CFSTATUS				X				
CFSTRUCT	X	X	X	X	X			
CHANNEL	X	X	X	X	X	X	X	X
CHSTATUS				X	X			
CLNTCONN	X	X	X	X	X			
CLUSCHL				X	X	X(2)	X(2)	X(2)
CLUSQ				X	X			
CLUSQMGR				X	X	X(2)	X(2)	X(2)
CLUSRCVR	X	X	X	X	X	X	X	X
CLUSSDR	X	X	X	X	X	X	X	X
CONNECT				X	X			
CONTROL				X		X	X	X
MANAGER	X			X		X		
NAMELIST	X	X	X	X	X			
PROCESS	X	X	X	X	X			
QALIAS	X	X	X	X	X			
QLOCAL	X	X	X	X	X			

Table 13. Valid operations and control panel actions for IBM MQ objects (continued)

Object	Alter	Define like	Manage (1)	List or Display	List with Filter	Perform	Start	Stop
QMODEL	X	X	X	X	X			
QREMOTE	X	X	X	X	X			
QSTATUS				X	X			
QUEUE	X	X	X	X	X			
RECEIVER	X	X	X	X	X	X	X	X
REQUESTER	X	X	X	X	X	X	X	X
SECURITY	X			X		X		
SENDER	X	X	X	X	X	X	X	X
SERVER	X	X	X	X	X	X	X	X
SVRCONN	X	X	X	X	X		X	X
STGCLASS	X	X	X	X	X			
SYSTEM				X		X	X	X

Note:
1. Provides **Delete** and other functions
2. Using the **List or Display** action

Object dispositions:

You can specify the *disposition* of the object with which you need to work. The disposition signifies where the object **definition** is kept, and how the object behaves.

The disposition is significant only if you are working with any of the following object types:
- queues
- channels
- processes
- namelists
- storage classes
- authentication information objects

If you are working with other object types, the disposition is disregarded.

Permitted values are:

Q	QMGR. The object definitions are on the page set of the queue manager and are accessible only by the queue manager.
C	COPY. The object definitions are on the page set of the queue manager and are accessible only by the queue manager. They are local copies of objects defined as having a disposition of GROUP.
P	PRIVATE. The object definitions are on the page set of the queue manager and are accessible only by the queue manager. The objects have been defined as having a disposition of QMGR or COPY.
G	GROUP. The object definitions are in the shared repository, and are accessible by all queue managers in the queue-sharing group.
S	SHARED. This disposition applies only to local queues. The queue definitions are in the shared repository, and are accessible by all queue managers in the queue-sharing group.

A ALL. If the action queue manager is either the target queue manager, or *, objects of **all** dispositions are included; otherwise, objects of QMGR and COPY dispositions only are included. This is the default.

Selecting a queue manager, defaults, and levels using the ISPF control panel:

You can use the CSQOREXX exec in ISPF to control your queue managers.

While you are viewing the initial panel, you are not connected to any queue manager. However, as soon as you press Enter, you are connected to the queue manager, or a queue manager in the queue-sharing group named in the **Connect name** field. You can leave this field blank; this means that you are using the default queue manager for batch applications. This is defined in CSQBDEFV (see Task 19: Set up Batch, TSO, and RRS adapters for information about this).

Use the **Target queue manager** field to specify the queue manager where the actions you request are to be performed. If you leave this field blank, it defaults to the queue manager specified in the **Connect name** field. You can specify a target queue manager that is not the one you connect to. In this case, you would normally specify the name of a remote queue manager object that provides a queue manager alias definition (the name is used as the *ObjectQMgrName* when opening the command input queue). To do this, you must have suitable queues and channels set up to access the remote queue manager.

The **Action queue manager** allows you to specify a queue manager that is in the same queue-sharing group as the queue manager specified in the **Target queue manager** field to be the queue manager where the actions you request are to be performed. If you specify * in this field, the actions you request are performed on all queue managers in the queue-sharing group. If you leave this field blank, it defaults to the value specified in the **Target queue manager** field. The **Action queue manager** field corresponds to using the CMDSCOPE command modifier described in The MQSC commands.

Queue manager defaults

If you leave any queue manager fields blank, or choose to connect to a queue-sharing group, a secondary window opens when you press Enter. This window confirms the names of the queue managers you will be using. Press Enter to continue. When you return to the initial panel after having made some requests, you find fields completed with the actual names.

Queue manager levels

The Operations and Control panels work satisfactorily only with queue managers that are running on z/OS, and with command levels that match that of the panels, currently 710 or 800.

If these conditions are not met, it is likely that actions work only partially, incorrectly, or not at all, and that the replies from the queue manager are not recognized.

If the action queue manager is not at command level 800, some fields are not displayed, and some values cannot be entered. A few objects and actions are disallowed. In such cases, a secondary window opens asking for you to confirm that you want to proceed.

Using the function keys and command line with the ISPF control panels:

To use the panels, you must use the function keys or enter the equivalent commands in the ISPF control panel command area.

- Function keys
  - Processing your actions
  - "Displaying IBM MQ user messages"
  - Canceling your actions
  - Getting help
- Using the command line

Function keys

The function keys have special settings for IBM MQ. (This means that you cannot use the ISPF default values for the function keys; if you have previously used the KEYLIST OFF ISPF command anywhere, you must type KEYLIST ON in the command area of any operations and control panel and then press Enter to enable the IBM MQ settings.)

These function key settings can be displayed on the panels, as shown in Figure 43 on page 280. If the settings are not shown, type PFSHOW in the command area of any operations and control panel and then press Enter. To remove the display of the settings, use the command PFSHOW OFF.

The function key settings in the operations and control panels conform to CUA standards. Although you can change the key setting through normal ISPF procedures (such as the KEYLIST utility), you are not recommended to do so.

Note: Using the PFSHOW and KEYLIST commands affects any other logical ISPF screens that you have, and their settings remain when you leave the operations and control panels.

Processing your actions

Press Enter to carry out the action requested on a panel. The information from the panel is sent to the queue manager for processing.

Each time you press Enter in the panels, IBM MQ generates one or more operator messages. If the operation was successful, you get confirmation message CSQ9022I, otherwise you get some error messages.

Displaying IBM MQ user messages

Press function key F10 in any panel to see the IBM MQ user messages.

Canceling your actions

On the initial panel, both F3 and F12 exit the operations and control panels and return you to ISPF. No information is sent to the queue manager.

On any other panel, press function keys F3 or F12 to leave the current panel **ignoring any data you have typed since last pressing Enter**. Again, no information is sent to the queue manager.

- F3 takes you straight back to the initial panel.
- F12 takes you back to the previous panel.

Getting help

Each panel has help panels associated with it. The help panels use the ISPF protocols:

- Press function key F1 on any panel to see general help (extended help) about the task.
- Press function key F1 with the cursor on any field to see specific help about that field.
- Press function key F5 from any field help panel to get the general help.

- Press function key F3 to return to the base panel, that is, the panel from which you pressed function key F1.
- Press function key F6 from any help panel to get help about the function keys.

If the help information carries on into a second or subsequent pages, a **More** indicator is displayed in the upper right of the panel. Use these function keys to navigate through the help pages:

- F11 to get to the next help page (if there is one).
- F10 to get back to the previous help page (if there is one).

Using the command line

You never need to use the command line to issue the commands used by the operations and control panels because they are available from function keys. The command line is provided to allow you to enter normal ISPF commands (like PFSHOW).

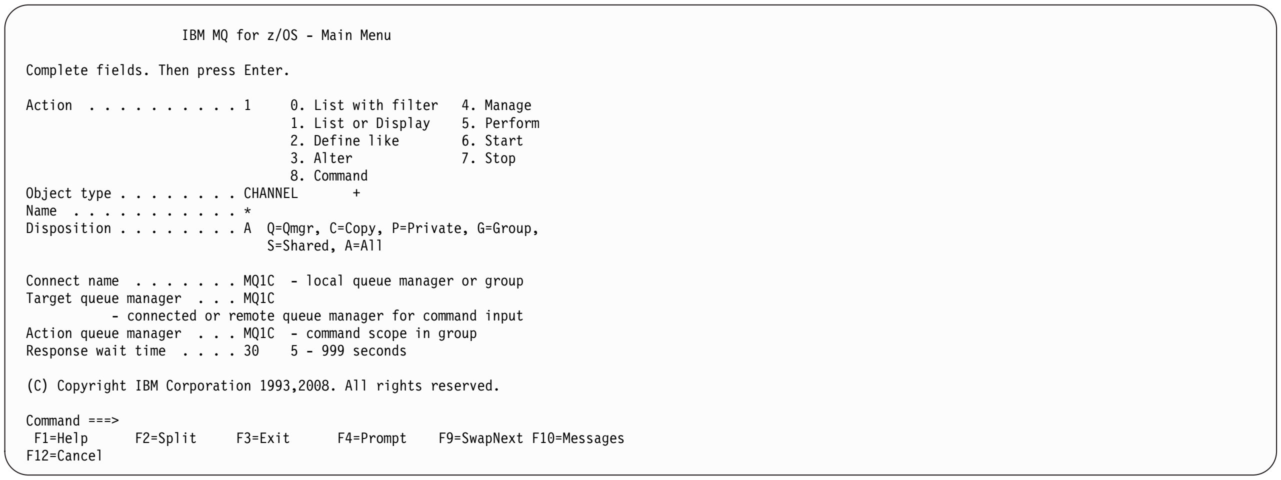
The ISPF command PANELID ON displays the name of the current CSQOREXX panel.

The command line is initially displayed in the default position at the bottom of the panels, regardless of what ISPF settings you have. You can use the SETTINGS ISPF command from any of the operations and control panels to change the position of the command line. The settings are remembered for subsequent sessions with the operations and control panels.

Using the operations and control panels

Use this topic to investigate the initial control panel displayed from CSQOREXX

Figure 43 shows the panel that is displayed when you start a panel session.



```
                    IBM MQ for z/OS - Main Menu

Complete fields. Then press Enter.

Action  . . . . . . . . . . 1     0. List with filter   4. Manage

```

Figure 43. The IBM MQ operations and control initial panel

From this panel you can perform actions such as:

- Choose the local queue manager you want and whether you want the commands issued on that queue manager, on a remote queue manager, or on another queue manager in the same queue-sharing group as the local queue manager. Over type the queue manager name if you need to change it.
- Select the action you want to perform by typing in the appropriate number in the **Action** field.
- Specify the object type that you want to work with. Press function key F1 for help about the object types if you are not sure what they are.
- Specify the disposition of the object type that you want to work with.

- Display a list of objects of the type specified. Type in an asterisk (*) in the **Name** field and press Enter to display a list of objects (of the type specified) that have already been defined on the action queue manager. You can then select one or more objects to work with in sequence. All the actions are available from the list.

Note: You are recommended to make choices that result in a list of objects being displayed, and then work from that list. Use the **Display** action, because that is allowed for all object types.

Using the Command Facility

Use the editor to enter or amend MQSC commands to be passed to the queue manager.

From the primary panel, CSQOPRIA, select option **8 Command**, to start the Command Facility.

You are presented with an edit session of a sequential file, *prefix*.CSQUTIL.COMMANDS, used as input to the CSQUTIL COMMAND function; see Issuing commands to IBM MQ.

You do not need to prefix commands with the command prefix string (CPF).

You can continue MQSC commands on subsequent lines by terminating the current line with the continuation characters **+** or **-**. Alternatively, use line edit mode to provide long MQSC commands or the values of long attribute values within the command.

line edit

To use line edit, move the cursor to the appropriate line in the edit panel and use **F4** to display a single line in a scrollable panel. A single line can be up to 32 760 bytes of data.

To leave line edit:

- **F3 exit** saves changes made to the line and exits
- **F12 cancel** returns to the edit panel discarding changes made to the line.

To discard changes made in the edit session, use **F12 cancel** to terminate the edit session leaving the contents of the file unchanged. Commands are not executed.

Executing commands

When you have finished entering MQSC commands, terminate the edit session with **F3 exit** to save the contents of the file and invoke CSQUTIL to pass the commands to the queue manager. The output from command processing is held in file *prefix*.CSQUTIL.OUTPUT. An edit session opens automatically on this file so that you can view the responses. Press **F3 exit** to exit this session and return to the main menu.

Working with IBM MQ objects

Many of the tasks described in this documentation involve manipulating IBM MQ objects. The object types are queue managers, queues, process definitions, namelists, channels, client connection channels, listeners, services, and authentication information objects.

- Defining simple queue objects
- Defining other types of objects
- Working with object definitions
- Working with namelists

Defining simple queue objects

To define a new object, use an existing definition as the basis for it. You can do this in one of three ways:

- By selecting an object that is a member of a list displayed as a result of options selected on the initial panel. You then enter action type 2 (**Define like**) in the action field next to the selected object. Your new object has the attributes of the selected object, except the disposition. You can then change any attributes in your new object as you require.
- On the initial panel, select the **Define like** action type, enter the type of object that you are defining in the **Object type** field, and enter the name of a specific existing object in the **Name** field. Your new object has the same attributes as the object you named in the **Name** field, except the disposition. You can then change any attributes in your new object definition as you require.
- By selecting the **Define like** action type, specifying an object type and then leaving the **Name** field blank. You can then define your new object and it has the default attributes defined for your installation. You can then change any attributes in your new object definition as you require.

Note: You do not enter the name of the object you are defining on the initial panel, but on the **Define** panel you are presented with.

The following example demonstrates how to define a local queue using an existing queue as a template.

Defining a local queue

To define a local queue object from the operations and control panels, use an existing queue definition as the basis for your new definition. There are several panels to complete. When you have completed all the panels and you are satisfied that the attributes are correct, press Enter to send your definition to the queue manager, which then creates the actual queue.

Use the **Define like** action either on the initial panel or against an object entry in a list displayed as a result of options selected on the initial panel.

For example, starting from the initial panel, complete these fields:

Action	2 (Define like)
Object type	QLOCAL
Name	QUEUE.YOU.LIKE. This is the name of the queue that provides the attributes for your new queue.

Press Enter to display the **Define a Local Queue** panel. The queue name field is blank so that you can supply the name for the new queue. The description is that of the queue upon which you are basing this new definition. Over type this field with your own description for the new queue.

The values in the other fields are those of the queue upon which you are basing this new queue, except the disposition. You can over type these fields as you require. For example, type `Y` in the **Put enabled** field (if it is not already Y) if suitably authorized applications can put messages on this queue.

You get field help by moving the cursor into a field and pressing function key F1. Field help provides information about the values that can be used for each attribute.

When you have completed the first panel, press function key F8 to display the second panel.

Hints:

1. Do *not* press Enter at this stage, otherwise the queue will be created before you have a chance to complete the remaining fields. (If you do press Enter prematurely, do not worry; you can always alter your definition later on.)
2. Do not press function keys F3 or F12, or the data you typed will be lost.

Press function key F8 repeatedly to see and complete the remaining panels, including the trigger definition, event control, and backout reporting panels.

When your local queue definition is complete

When your definition is complete, press Enter to send the information to the queue manager for processing. The queue manager creates the queue according to the definition you have supplied. If you do not want the queue to be created, press function key F3 to exit and cancel the definition.

Defining other types of objects

To define other types of object, use an existing definition as the base for your new definition as explained in Defining a local queue.

Use the **Define like** action either on the initial panel or against an object entry in a list displayed as a result of options selected on the initial panel.

For example, starting from the initial panel, complete these fields:

Action	2 (Define like)
Object type	QALIAS, NAMELIST, PROCESS, CHANNEL, and other resource objects.
Name	Leave blank or enter the name of an existing object of the same type.

Press Enter to display the corresponding DEFINE panels. Complete the fields as required and then press Enter again to send the information to the queue manager.

Like defining a local queue, defining another type of object generally requires several panels to be completed. Defining a namelist requires some additional work, as described in "Working with namelists" on page 284.

Working with object definitions

When an object has been defined, you can specify an action in the **Action** field, to alter, display, or manage it.

In each case, you can either:

- Select the object you want to work with from a list displayed as a result of options selected on the initial panel. For example, having entered 1 in the **Action** field to display objects, `Queue` in the **Object type** field, and * in the **Name** field, you are presented with a list of all queues defined in the system. You can then select from this list the queue with which you need to work.
- Start from the initial panel, where you specify the object you are working with by completing the **Object type** and **Name** fields.

Altering an object definition

To alter an object definition, specify action 3 and press Enter to see the ALTER panels. These panels are very similar to the DEFINE panels. You can alter the values you want. When your changes are complete, press Enter to send the information to the queue manager.

Displaying an object definition

If you want to see the details of an object without being able to change them, specify action 1 and press Enter to see the DISPLAY panels. Again, these panels are similar to the DEFINE panels except that you cannot change any of the fields. Change the object name to display details of another object.

Deleting an object

To delete an object, specify action 4 (Manage) and the **Delete** action is one of the actions presented on the resulting menu. Select the **Delete** action.

You are asked to confirm your request. If you press function key F3 or F12, the request is canceled. If you press Enter, the request is confirmed and passed to the queue manager. The object you specified is then deleted.

Note: You cannot delete most types of channel object unless the channel initiator is started.

Working with namelists

When working with namelists, proceed as you would for other objects.

For the actions DEFINE LIKE or ALTER, press function key F11 to add names to the list or to change the names in the list. This involves working with the ISPF editor and all the normal ISPF edit commands are available. Enter each name in the namelist on a separate line.

When you use the ISPF editor in this way, the function key settings are the normal ISPF settings, and **not** those used by the other operations and control panels.

If you need to specify lowercase names in the list, specify CAPS(OFF) on the editor panel command line. When you do this, all the namelists that you edit in the future are in lowercase until you specify CAPS(ON).

When you have finished editing the namelist, press function key F3 to end the ISPF edit session. Then press Enter to send the changes to the queue manager.

Attention: If you do not press Enter at this stage but press function key F3 instead, you lose any updates that you have typed in.

Implementing the system using multiple cluster transmission queues

It makes no difference if the channel is used in a single cluster, or an overlapping cluster. When the channel is selected and started, the channel selects the transmission queue depending on the definitions.

About this task

See "Using the automatic definition of queues and switching" if you are using the DEFCLXQ option.

See "Changing your cluster-sender channels using a phased approach" if you are using a staged approach.

Using the automatic definition of queues and switching:

Use this option if you are planning on using the DEFCLXQ option. There will be a queue created for every channel, and every new channel.

Procedure

1. Review the definition of the SYSTEM.CLUSTER.TRANSMIT.MODEL.QUEUE and change the attributes if required. This queue is defined in member `SCSQPROC(csq4insx)`.
2. Create the SYSTEM.CLUSTER.TRANSMIT.MODEL.QUEUE model queue.
3. Apply security policies for this model queue, and the SYSTEM.CLUSTER.TRANSMIT.** queues. For z/OS the channel initiator started task user ID needs:
   - Control access to CLASS(MQADMIN) for `ssid.CONTEXT.SYSTEM.CLUSTER.TRANSMIT.channelname`
   - Update access to CLASS(MQQUEUE) for `ssid.SYSTEM.CLUSTER.TRANSMIT.channelname`

Changing your cluster-sender channels using a phased approach:

This process allows you to move to the new cluster-sender channels at various times to suit the needs of your enterprise.

Before you begin

- Identify your business applications, and which channels are used.
- For the queues you use, display the clusters they are in.
- Display the channels to show the connection names, the names of the remote queue managers, and which clusters the channel supports.

About this task

- Create a transmission queue. On z/OS you might want to consider which page set you use for the queue.
- Set up security policy for the queue.
- Change any queue monitoring to include this queue name.
- Decide which channels are to use this transmission queue. The channels should have a similar name, so generic characters ' * ' in the CLCHNAME identify the channel.
- When you are ready to use the new function, alter the transmission queue to specify the name of the channels to use this transmission queue. For example CLUSTER1.TOPARIS, or CLUSTER1.* or *.TOPARIS
- Start the channels

Procedure

1. Use the `DIS CLUSQMGR(xxxx) XMITQ` command to display the cluster sender channels defined in the cluster, where *xxxx* is the name of the remote queue manager.
2. Set up the security profile for the transmission queue and give the queue access to the channel initiator.
3. Define the transmission queue to be used, and specify USAGE(XMITQ) INDXTYPE(CORRELID) SHARE and CLCHNAME(*value*) The channel initiator started task user ID needs the following access:

   ```
   alter class(MQADMIN) ssid.CONTEXT.SYSTEM.CLUSTER.TRANSMIT.channel
   update class(MQQUEUE ssid.SYSTEM.CLUSTER.TRANSMIT.channel
   ```

   and the user ID using the SWITCH command needs the following access:

   ```
   alter cl(MQADMIN) ssid.QUEUE.queuename
   ```
4. Stop and restart the channels.

   The channel change occurs when the channel starts using an MQSC command, or you use CSQUTIL. You can identify which channels need to be restarted using the `SWITCH CHANNEL(*)STATUS` of CSQUTIL

   If you have problems when the channel is started, stop the channel, resolve the problems, and restart the channel.

   Note that you can change the CLCHNAME attribute as often as you need to.

   The value of CLCHNAME used is the one when the channel is started, so you can change the CLCHNAME definition while the channel continues to use the definitions from the time that it started. The channel uses the new definition when it is restarted.

Undoing a change

You need to have a process to backout a change if it the results are not as you expect.

What can go wrong?

If the new transmission queue is not what you expect:

1. Check the CLCHNAME is as you expect
2. Review the job log to check if the switch process has finished. If not, wait and check the new transmission queue of the channel later.

If you are using multiple cluster transmission queues, it is important that you design the transmission queues definitions explicitly and avoid complicated overlapping configuration. In this way, you can make sure that if there are problems, you can go back to the original queues and configuration.

If you encounter problems during the move to using a different transmission queue, you must resolve any problems before you can proceed with the change.

An existing change request must complete before a new change request can be made. For example, you:

1. Define a new transmission queue with a maximum depth of one and there are 10 messages waiting to be sent.
2. Change the transmission queue to specify the channel name in the CLCHNAME parameter.
3. Stop and restart the channel. The attempt to move the messages fails and reports the problems.
4. Change the CLCHNAME parameter on the transmission queue to be blank.
5. Stop and restart the channel. The channel continues to try and complete the original request, so the channel continues to use the new transmission queue.
6. Need to resolve the problems and restart the channel so the moving of messages completes successfully.

Next time the channel is restarted it picks up any changes, so if you had set CLCHNAME to blanks, the channel will not use the specified transmission queue.

In this example, changing the CLCHNAME on the transmission queue to blanks does not necessarily mean that the channel uses the SYSTEM.CLUSTER.TRANSMIT queue, as there might be other transmission queues whose CLCHNAME parameter match the channel name. For example, a generic name, or the queue manager attribute DEFCLXQ might be set to channel, so the channel uses a dynamic queue instead of the SYSTEM.CLUSTER.TRANSMIT queue.

Writing programs to administer IBM MQ

You can write your own application programs to administer a queue manager. Use this topic to understand the requirements for writing your own administration programs.

Start of General-use programming interface information

This set of topics contains hints and guidance to enable you to issue IBM MQ commands from an IBM MQ application program.

Note: In this topic, the MQI calls are described using C-language notation. For typical invocations of the calls in the COBOL, PL/I, and assembler languages, see Function calls manual.

Understanding how it all works

In outline, the procedure for issuing commands from an application program is as follows:

1. Build an IBM MQ command into a type of IBM MQ message called a *request message*. The command can be in MQSC or PCF format.
2. Send (use **MQPUT**) this message to a special queue called the system-command input queue. The IBM MQ command processor runs the command.
3. Retrieve (use **MQGET**) the results of the command as *reply messages* on the reply-to queue. These messages contain the user messages that you need to determine whether your command was successful and, if it was, what the results were.

Then it is up to your application program to process the results.

This set of topics contains:

Preparing queues for administration programs

Administration programs require a number of predefined queues for system command input and receiving responses.

This section applies to commands in the MQSC format. For the equivalent in PCF, see “Using Programmable Command Formats” on page 7.

Before you can issue any **MQPUT** or **MQGET** calls, you must first define, and then open, the queues you are going to use.

Defining the system-command input queue

The system-command input queue is a local queue called SYSTEM.COMMAND.INPUT. The supplied CSQINP2 initialization data set, thlqual.SCSQPROC(CSQ4INSG), contains a default definition for the system-command input queue. For compatibility with IBM MQ on other platforms, an alias of this queue, called SYSTEM.ADMIN.COMMAND.QUEUE is also supplied. See Sample definitions supplied with IBM MQ for more information.

Defining a reply-to queue

You must define a reply-to queue to receive reply messages from the IBM MQ command processor. It can be any queue with attributes that allow reply messages to be put on it. However, for normal operation, specify these attributes:

- USAGE(NORMAL)
- NOTRIGGER (unless your application uses triggering)

Avoid using persistent messages for commands, but if you choose to do so, the reply-to queue must not be a temporary dynamic queue.

The supplied CSQINP2 initialization data set, thlqual.SCSQPROC(CSQ4INSG), contains a definition for a model queue called SYSTEM.COMMAND.REPLY.MODEL. You can use this model to create a dynamic reply-to queue.

Note: Replies generated by the command processor can be up to 15 000 bytes in length.

If you use a permanent dynamic queue as a reply-to queue, your application should allow time for all PUT and GET operations to complete before attempting to delete the queue, otherwise MQRC2055 (MQRC_Q_NOT_EMPTY) can be returned. If this occurs, try the queue deletion again after a few seconds.

Opening the system-command input queue

Before you can open the system-command input queue, your application program must be connected to your queue manager. Use the MQI call **MQCONN** or **MQCONNX** to do this.

Then use the MQI call **MQOPEN** to open the system-command input queue. To use this call:

1. Set the *Options* parameter to MQOO_OUTPUT
2. Set the MQOD object descriptor fields as follows:

   ObjectType
   MQOT_Q (the object is a queue)

   ObjectName
   SYSTEM.COMMAND.INPUT

   ObjectQMgrName
   If you want to send your request messages to your local queue manager, leave this field blank. This means that your commands are processed locally.

   If you want your IBM MQ commands to be processed on a remote queue manager, put its name here. You must also have the correct queues and links set up, as described in Distributed queuing and clusters.

Opening a reply-to queue

To retrieve the replies from an IBM MQ command, you must open a reply-to queue. One way of doing this is to specify the model queue, SYSTEM.COMMAND.REPLY.MODEL in an **MQOPEN** call, to create a permanent dynamic queue as the reply-to queue. To use this call:

1. Set the *Options* parameter to MQOO_INPUT_SHARED
2. Set the MQOD object descriptor fields as follows:

   ObjectType
   MQOT_Q (the object is a queue)

   ObjectName
   The name of the reply-to queue. If the queue name you specify is the name of a model queue object, the queue manager creates a dynamic queue.

   ObjectQMgrName
   To receive replies on your local queue manager, leave this field blank.

   DynamicQName
   Specify the name of the dynamic queue to be created.

Using the command server

The command server is an IBM MQ component that works with the command processor component. You can send formatted messages to the command server which interprets the messages, runs the administration requests, and sends responses back to your administration application.

The command server reads request messages from the system-command input queue, verifies them, and passes the valid ones as commands to the command processor. The command processor processes the commands and puts any replies as reply messages on to the reply-to queue that you specify. The first reply message contains the user message CSQN205I. See “Interpreting the reply messages from the command server” on page 293 for more information. The command server also processes channel initiator and queue-sharing group commands, wherever they are issued from.

Identifying the queue manager that processes your commands

The queue manager that processes the commands you issue from an administration program is the queue manager that owns the system-command input queue that the message is put onto.

Starting the command server

Normally, the command server is started automatically when the queue manager is started. It becomes available as soon as the message CSQ9022I 'START QMGR' NORMAL COMPLETION is returned from the START QMGR command. The command server is stopped when all the connected tasks have been disconnected during the system termination phase.

You can control the command server yourself using the START CMDSERV and STOP CMDSERV commands. To prevent the command server starting automatically when IBM MQ is restarted, you can add a STOP CMDSERV command to your CSQINP1 or CSQINP2 initialization data sets. However, this is not recommended as it prevents any channel initiator or queue-sharing group commands being processed.

The STOP CMDSERV command stops the command server as soon as it has finished processing the current message, or immediately if no messages are being processed.

If the command server has been stopped by a STOP CMDSERV command in the program, no other commands from the program can be processed. To restart the command server, you must issue a START CMDSERV command from the z/OS console.

If you stop and restart the command server while the queue manager is running, all the messages that are on the system-command input queue when the command server stops are processed when the command server is restarted. However, if you stop and restart the queue manager after the command server is stopped, only the persistent messages on the system-command input queue are processed when the command server is restarted. All nonpersistent messages on the system-command input queue are lost.

Sending commands to the command server

For each command, you build a message containing the command, then put it onto the system-command input queue.

Building a message that includes IBM MQ commands

You can incorporate IBM MQ commands in an application program by building request messages that include the required commands. For each such command you:

1. Create a buffer containing a character string representing the command.
2. Issue an **MQPUT** call specifying the buffer name in the `buffer` parameter of the call.

The simplest way to do this in C is to define a buffer using 'char'. For example:

```
char message_buffer[ ] = "ALTER QLOCAL(SALES) PUT(ENABLED)";
```

When you build a command, use a null-terminated character string. Do not specify a command prefix string (CPF) at the start of a command defined in this way. This means that you do not have to alter your command scripts if you want to run them on another queue manager. However, you must take into account that a CPF is included in any response messages that are put onto the reply-to queue.

The command server folds all lowercase characters to uppercase unless they are inside quotation marks.

Commands can be any length up to a maximum 32 762 characters.

Putting messages on the system-command input queue

Use the **MQPUT** call to put request messages containing commands on the system-command input queue. In this call you specify the name of the reply-to queue that you have already opened.

To use the **MQPUT** call:

1. Set these **MQPUT** parameters:

   Hconn The connection handle returned by the **MQCONN** or **MQCONNX** call.

   Hobj The object handle returned by the **MQOPEN** call for the system-command input queue.

   BufferLength
   The length of the formatted command.

   Buffer The name of the buffer containing the command.
2. Set these MQMD fields:

   MsgType
   MQMT_REQUEST

   Format MQFMT_STRING or MQFMT_NONE

   If you are not using the same code page as the queue manager, set *CodedCharSetId* as appropriate and set MQFMT_STRING, so that the command server can convert the message. Do not set MQFMT_ADMIN, as that causes your command to be interpreted as PCF.

   ReplyToQ
   Name of your reply-to queue.

   ReplyToQMgr
   If you want replies sent to your local queue manager, leave this field blank. If you want your IBM MQ commands to be sent to a remote queue manager, put its name here. You must also have the correct queues and links set up, as described in Distributed queuing and clusters.
3. Set any other MQMD fields, as required. You should normally use nonpersistent messages for commands.
4. Set any *PutMsgOpts* options, as required.

   If you specify MQPMO_SYNCPOINT (the default), you must follow the **MQPUT** call with a syncpoint call.

Using MQPUT1 and the system-command input queue

If you want to put just one message on the system-command input queue, you can use the **MQPUT1** call. This call combines the functions of an **MQOPEN** , followed by an **MQPUT** of one message, followed by an **MQCLOSE** , all in one call. If you use this call, modify the parameters accordingly. See Putting one message on a queue using the MQPUT1 call for details.

Retrieving replies to your commands

The command server sends a response to a reply queue for each request message it receives. Any administration application must receive, and handle the reply messages.

When the command processor processes your commands, any reply messages are put onto the reply-to queue specified in the **MQPUT** call. The command server sends the reply messages with the same persistence as the command message it received.

Waiting for a reply

Use the **MQGET** call to retrieve a reply from your request message. One request message can produce several reply messages. For details, see "Interpreting the reply messages from the command server" on page 293.

You can specify a time interval that an **MQGET** call waits for a reply message to be generated. If you do not get a reply, use the checklist beginning in topic "If you do not receive a reply" on page 293.

To use the **MQGET** call:

1. Set these parameters:

   Hconn The connection handle returned by the **MQCONN** or **MQCONNX** call.

   Hobj The object handle returned by the **MQOPEN** call for the reply-to queue.

   Buffer The name of the area to receive the reply.

   BufferLength
   The length of the buffer to receive the reply. This must be a minimum of 80 bytes.
2. To ensure that you only get the responses from the command that you issued, you must specify the appropriate *MsgId* and *CorrelId* fields. These depend on the report options, MQMD_REPORT, you specified in the **MQPUT** call:

   MQRO_NONE
   Binary zero, '00...00' (24 nulls).

   MQRO_NEW_MSG_ID
   Binary zero, '00...00' (24 nulls).

   This is the default if none of these options has been specified.

   MQRO_PASS_MSG_ID
   The *MsgId* from the **MQPUT** .

   MQRO_NONE
   The *MsgId* from the **MQPUT** call.

   MQRO_COPY_MSG_ID_TO_CORREL_ID
   The *MsgId* from the **MQPUT** call.

   This is the default if none of these options has been specified.

   MQRO_PASS_CORREL_ID
   The *CorrelId* from the **MQPUT** call.

   For more details on report options, see Report options and message flags.
3. Set the following *GetMsgOpts* fields:

   Options
   MQGMO_WAIT

If you are not using the same code page as the queue manager, set MQGMO_CONVERT, and set *CodedCharSetId* as appropriate in the MQMD.

WaitInterval
For replies from the local queue manager, try 5 seconds. Coded in milliseconds, this becomes 5 000. For replies from a remote queue manager, and channel control and status commands, try 30 seconds. Coded in milliseconds, this becomes 30 000.

Discarded messages

If the command server finds that a request message is not valid, it discards this message and writes the message CSQN205I to the named reply-to queue. If there is no reply-to queue, the CSQN205I message is put onto the dead-letter queue. The return code in this message shows why the original request message was not valid:

00D5020F	It is not of type MQMT_REQUEST.
00D50210	It has zero length.
00D50212	It is longer than 32 762 bytes.
00D50211	It contains all blanks.
00D5483E	It needed converting, but *Format* was not MQFMT_STRING.
Other	See Command server codes

The command server reply message descriptor

For any reply message, the following MQMD message descriptor fields are set:

MsgType	MQMT_REPLY
Feedback	MQFB_NONE
Encoding	MQENC_NATIVE
Priority	As for the MQMD in the message you issued.
Persistence	As for the MQMD in the message you issued.
CorrelId	Depends on the **MQPUT** report options.
ReplyToQ	None.

The command server sets the *Options* field of the MQPMO structure to MQPMO_NO_SYNCPOINT. This means that you can retrieve the replies as they are created, rather than as a group at the next syncpoint.

Interpreting the reply messages from the command server

Each request message correctly processed by IBM MQ produces at least two reply messages. Each reply message contains a single IBM MQ user message.

The length of a reply depends on the command that was issued. The longest reply you can get is from a DISPLAY NAMELIST, and that can be up to 15 000 bytes in length.

The first user message, CSQN205I, always contains:

- A count of the replies (in decimal), which you can use as a counter in a loop to get the rest of the replies. The count includes this first message.
- The return code from the command preprocessor.
- A reason code, which is the return code from the command processor.

This message does not contain a CPF.

For example:

```
CSQN205I    COUNT=    4, RETURN=0000000C, REASON=00000008
```

The COUNT field is 8 bytes long and is right-justified. It always starts at position 18, that is, immediately after 'COUNT='. The RETURN field is 8 bytes long in character hexadecimal and is immediately after 'RETURN=' at position 35. The REASON field is 8 bytes long in character hexadecimal and is immediately after 'REASON=' at position 52.

If the RETURN= value is 00000000 and the REASON= value is 00000004, the set of reply messages is incomplete. After retrieving the replies indicated by the CSQN205I message, issue a further **MQGET** call to wait for a further set of replies. The first message in the next set of replies is again CSQN205I, indicating how many replies there are, and whether there are still more to come.

See the IBM MQ for z/OS messages, completion, and reason codes documentation for more details about the individual messages.

If you are using a non-English language feature, the text and layout of the replies are different from those shown here. However, the size and position of the count and return codes in message CSQN205I are the same.

If you do not receive a reply

There are a series of steps you can take if you do not receive a response to request to the command server.

If you do not receive a reply to your request message, work through this checklist:

- Is the command server running?
- Is the `WaitInterval` long enough?
- Are the system-command input and reply-to queues correctly defined?
- Were the **MQOPEN** calls to these queues successful?
- Are both the system-command input and reply-to queues enabled for **MQPUT** and **MQGET** calls?
- Have you considered increasing the MAXDEPTH and MAXMSGL attributes of your queues?
- Are you are using the `CorrelId` and `MsgId` fields correctly?
- Is the queue manager still running?
- Was the command built correctly?
- Are all your remote links defined and operating correctly?

- Were the **MQPUT** calls correctly defined?
- Has the reply-to queue been defined as a temporary dynamic queue instead of a permanent dynamic queue? (If the request message is persistent, you must use a permanent dynamic queue for the reply.)

When the command server generates replies but cannot write them to the reply-to queue that you specify, it writes them to the dead-letter queue.

Passing commands using MGCRE

With appropriate authorization, an application program can make requests to multiple queue managers using a z/OS service routine.

If you have the correct authorization, you can pass IBM MQ commands from your program to multiple queue managers by the MGCRE (SVC 34) z/OS service. The value of the CPF identifies the particular queue manager to which the command is directed. For information about CPFs, see User IDs for command security and command resource security and “Issuing queue manager commands” on page 266.

If you use MGCRE, you can use a Command and Response Token (CART) to get the direct responses to the command.

Examples of commands and their replies

Use this topic as a series of examples of commands to the command server and the responses from the command server.

Here are some examples of commands that could be built into IBM MQ messages, and the user messages that are the replies. Unless otherwise stated, each line of the reply is a separate message.
- Messages from a DEFINE command
- Messages from a DELETE command
- Messages from DISPLAY commands
- Messages from commands with CMDSCOPE
- Messages from commands that generate commands with CMDSCOPE

Messages from a DEFINE command

The following command:

```
DEFINE QLOCAL(Q1)
```

produces these messages:

```
CSQN205I    COUNT=    2, RETURN=00000000, REASON=00000000
CSQ9022I +CSQ1 CSQMMSGP ' DEFINE QLOCAL' NORMAL COMPLETION
```

These reply messages are produced on normal completion.

Messages from a DELETE command

The following command:

```
DELETE QLOCAL(Q2)
```

produces these messages:

```
CSQN205I    COUNT=    4, RETURN=0000000C, REASON=00000008
CSQM125I +CSQ1 CSQMUQLC QLOCAL (Q2) QSGDISP(QMGR) WAS NOT FOUND
CSQM090E +CSQ1 CSQMUQLC FAILURE REASON CODE X'00D44002'
CSQ9023E +CSQ1 CSQMUQLC ' DELETE QLOCAL' ABNORMAL COMPLETION
```

These messages indicate that a local queue called Q2 does not exist.

Messages from DISPLAY commands

The following examples show the replies from some DISPLAY commands.

Finding out the name of the dead-letter queue

If you want to find out the name of the dead-letter queue for a queue manager, issue this command from an application program:

```
DISPLAY QMGR DEADQ
```

The following three user messages are returned, from which you can extract the required name:

```
CSQN205I    COUNT=    3, RETURN=00000000, REASON=00000000
CSQM409I +CSQ1 QMNAME(CSQ1) DEADQ(SYSTEM.DEAD.QUEUE          )
CSQ9022I +CSQ1 CSQMDRTS ' DISPLAY QMGR' NORMAL COMPLETION
```

Messages from the DISPLAY QUEUE command

The following examples show how the results from a command depend on the attributes specified in that command.

Example 1

You define a local queue using the command:

```
DEFINE QLOCAL(Q1) DESCR('A sample queue') GET(ENABLED) SHARE
```

If you issue the following command from an application program:

```
DISPLAY QUEUE(Q1) SHARE GET DESCR
```

these three user messages are returned:

```
CSQN205I    COUNT=    3, RETURN=00000000, REASON=00000000
CSQM401I +CSQ1 QUEUE(Q1                       ) TYPE(
QLOCAL ) QSGDISP(QMGR   )
DESCR(A sample queue
) SHARE  GET(ENABLED  )
CSQ9022I +CSQ1 CSQMDMSG ' DISPLAY QUEUE' NORMAL COMPLETION
```

Note: The second message, CSQM401I, is shown here occupying four lines.

Example 2

Two queues have names beginning with the letter A:

- A1 is a local queue with its PUT attribute set to DISABLED.
- A2 is a remote queue with its PUT attribute set to ENABLED.

If you issue the following command from an application program:

```
DISPLAY QUEUE(A*) PUT
```

these four user messages are returned:

```
CSQN205I    COUNT=    4, RETURN=00000000, REASON=00000000
CSQM401I +CSQ1 QUEUE(A1                       ) TYPE(
QLOCAL ) QSGDISP(QMGR   )
PUT(DISABLED )
CSQM406I +CSQ1 QUEUE(A2                       ) TYPE(
QREMOTE ) PUT(ENABLED  )
CSQ9022I +CSQ1 CSQMDMSG ' DISPLAY QUEUE' NORMAL COMPLETION
```

Note: The second and third messages, CSQM401I and CSQM406I, are shown here occupying three and two lines.

Messages from the DISPLAY NAMELIST command

You define a namelist using the command:

```
DEFINE NAMELIST(N1) NAMES(Q1,SAMPLE_QUEUE)
```

If you issue the following command from an application program:

```
DISPLAY NAMELIST(N1) NAMES NAMCOUNT
```

the following three user messages are returned:

```
CSQN205I    COUNT=    3, RETURN=00000000, REASON=00000000
CSQM407I +CSQ1 NAMELIST(N1                          ) QS
GDISP(QMGR   ) NAMCOUNT(     2) NAMES(Q1
,SAMPLE_QUEUE                  )
CSQ9022I +CSQ1 CSQMDMSG ' DISPLAY NAMELIST' NORMAL COMPLETION
```

Note: The second message, CSQM407I, is shown here occupying three lines.

Messages from commands with CMDSCOPE

The following examples show the replies from commands that have been entered with the CMDSCOPE attribute.

Messages from the ALTER PROCESS command

The following command:

```
ALT PRO(V4) CMDSCOPE(*)
```

produces the following messages:

```
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000004
CSQN137I !MQ25 'ALT PRO' command accepted for CMDSCOPE(*), sent to 2
CSQN205I  COUNT=    5, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'ALT PRO' command responses from MQ26
CSQM125I !MQ26 CSQMMSGP PROCESS(V4) QSGDISP(QMGR) WAS NOT FOUND
CSQM090E !MQ26 CSQMMSGP FAILURE REASON CODE X'00D44002'
CSQ9023E !MQ26 CSQMMSGP ' ALT PRO' ABNORMAL COMPLETION
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'ALT PRO' command responses from MQ25
CSQ9022I !MQ25 CSQMMSGP ' ALT PRO' NORMAL COMPLETION
CSQN205I  COUNT=    2, RETURN=0000000C, REASON=00000008
CSQN123E !MQ25 'ALT PRO' command for CMDSCOPE(*) abnormal completion
```

These messages tell you that the command was entered on queue manager MQ25 and sent to two queue managers (MQ25 and MQ26). The command was successful on MQ25 but the process definition did not exist on MQ26, so the command failed on that queue manager.

Messages from the DISPLAY PROCESS command

The following command:

```
DIS PRO(V*) CMDSCOPE(*)
```

produces the following messages:

```
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000004
CSQN137I !MQ25 'DIS PRO' command accepted for CMDSCOPE(*), sent to 2
CSQN205I  COUNT=    5, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'DIS PRO' command responses from MQ26
CSQM408I !MQ26 PROCESS(V2) QSGDISP(COPY)
CSQM408I !MQ26 PROCESS(V3) QSGDISP(QMGR)
CSQ9022I !MQ26 CSQMDRTS ' DIS PROCESS' NORMAL COMPLETION
CSQN205I  COUNT=    7, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'DIS PRO' command responses from MQ25
CSQM408I !MQ25 PROCESS(V2) QSGDISP(COPY)
CSQM408I !MQ25 PROCESS(V2) QSGDISP(GROUP)
CSQM408I !MQ25 PROCESS(V3) QSGDISP(QMGR)
CSQM408I !MQ25 PROCESS(V4) QSGDISP(QMGR)
CSQ9022I !MQ25 CSQMDRTS ' DIS PROCESS' NORMAL COMPLETION
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000000
CSQN122I !MQ25 'DIS PRO' command for CMDSCOPE(*) normal completion
```

These messages tell you that the command was entered on queue manager MQ25 and sent to two queue managers (MQ25 and MQ26). Information is displayed about all the processes on each queue manager with names starting with the letter V.

Messages from the DISPLAY CHSTATUS command

The following command:

```
DIS CHS(VT) CMDSCOPE(*)
```

produces the following messages:

```
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000004
CSQN137I !MQ25 'DIS CHS' command accepted for CMDSCOPE(*), sent to 2
CSQN205I  COUNT=    4, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'DIS CHS' command responses from MQ25
CSQM422I !MQ25 CHSTATUS(VT) CHLDISP(PRIVATE) CONNAME( ) CURRENT STATUS(STOPPED)
CSQ9022I !MQ25 CSQXDRTS ' DIS CHS' NORMAL COMPLETION
CSQN205I  COUNT=    4, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'DIS CHS' command responses from MQ26
CSQM422I !MQ26 CHSTATUS(VT) CHLDISP(PRIVATE) CONNAME( ) CURRENT STATUS(STOPPED)
CSQ9022I !MQ26 CSQXDRTS ' DIS CHS' NORMAL COMPLETION
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000000
CSQN122I !MQ25 'DIS CHS' command for CMDSCOPE(*) normal completion
```

These messages tell you that the command was entered on queue manager MQ25 and sent to two queue managers (MQ25 and MQ26). Information is displayed about channel status on each queue manager.

Messages from the STOP CHANNEL command

The following command:

```
STOP CHL(VT) CMDSCOPE(*)
```

produces these messages:

```
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000004
CSQN137I !MQ25 'STOP CHL' command accepted for CMDSCOPE(*), sent to 2
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'STOP CHL' command responses from MQ25
CSQM134I !MQ25 CSQMTCHL STOP CHL(VT) COMMAND ACCEPTED
SQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'STOP CHL' command responses from MQ26
CSQM134I !MQ26 CSQMTCHL STOP CHL(VT) COMMAND ACCEPTED
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'STOP CHL' command responses from MQ26
CSQ9022I !MQ26 CSQXCRPS ' STOP CHL' NORMAL COMPLETION
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'STOP CHL' command responses from MQ25
CSQ9022I !MQ25 CSQXCRPS ' STOP CHL' NORMAL COMPLETION
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000000
CSQN122I !MQ25 'STOP CHL' command for CMDSCOPE(*) normal completion
```

These messages tell you that the command was entered on queue manager MQ25 and sent to two queue managers (MQ25 and MQ26). Channel VT was stopped on each queue manager.

Messages from commands that generate commands with CMDSCOPE

The following command:

```
DEF PRO(V2) QSGDISP(GROUP)
```

produces these messages:

```
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQM122I !MQ25 CSQMMSGP ' DEF PRO' COMPLETED FOR QSGDISP(GROUP)
CSQN138I !MQ25 'DEFINE PRO' command generated for CMDSCOPE(*), sent to 2
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'DEFINE PRO' command responses from MQ25
CSQ9022I !MQ25 CSQMMSGP ' DEFINE PROCESS' NORMAL COMPLETION
CSQN205I  COUNT=    3, RETURN=00000000, REASON=00000004
CSQN121I !MQ25 'DEFINE PRO' command responses from MQ26
CSQ9022I !MQ26 CSQMMSGP ' DEFINE PROCESS' NORMAL COMPLETION
CSQN205I  COUNT=    2, RETURN=00000000, REASON=00000000
CSQN122I !MQ25 'DEFINE PRO' command for CMDSCOPE(*) normal completion
```

These messages tell you that the command was entered on queue manager MQ25. When the object was created on the shared repository, another command was generated and sent to all the active queue managers in the queue-sharing group (MQ25 and MQ26).

Managing IBM MQ resources on z/OS

z/OS

Use the links in this topic to find out how to manage the resources used by IBM MQ for z/OS, for example, managing log files, data sets, page sets, buffer pools, and coupling facility structures.

Use the following links for details of the different administrative tasks you might have to complete while using IBM MQ for z/OS:

- "Managing the logs"
- "Managing the bootstrap data set (BSDS)" on page 309
- "Managing page sets" on page 317
- "How to back up and recover page sets" on page 323
- "How to back up and restore queues using CSQUTIL" on page 327
- "Managing buffer pools" on page 327
- "Managing queue-sharing groups and shared queues" on page 328

Managing the logs

Use this topic to understand how to manage your IBM MQ log files, including the log archiving process, using log record compression, log record recovery, and printing log records.

This topic describes the tasks involved in managing the IBM MQ logs. It contains these sections:

Archiving logs with the ARCHIVE LOG command:

An authorized operator can archive the current IBM MQ active log data sets whenever required using the ARCHIVE LOG command.

When you issue the ARCHIVE LOG command, IBM MQ truncates the current active log data sets, then runs an asynchronous offload process, and updates the BSDS with a record of the offload process.

The ARCHIVE LOG command has a MODE(QUIESCE) option. With this option, IBM MQ jobs and users are quiesced after a commit point, and the resulting point of consistency is captured in the current active log before it is offloaded.

Consider using the MODE(QUIESCE) option when planning a backup strategy for off site recovery. It creates a system-wide point of consistency, which minimizes the number of data inconsistencies when the archive log is used with the most current backup page set copy during recovery. For example:

```
ARCHIVE LOG MODE(QUIESCE)
```

If you issue the ARCHIVE LOG command without specifying a TIME parameter, the quiesce time period defaults to the value of the QUIESCE parameter of the CSQ6ARVP macro. If the time required for the ARCHIVE LOG MODE(QUIESCE) to complete is less than the time specified, the command completes successfully; otherwise, the command fails when the time period expires. You can specify the time period explicitly by using the TIME option, for example:

```
ARCHIVE LOG MODE(QUIESCE) TIME(60)
```

This command specifies a quiesce period of up to 60 seconds before ARCHIVE LOG processing occurs.

Attention: Using the TIME option when time is critical can significantly disrupt IBM MQ availability for all jobs and users that use IBM MQ resources.

By default, the command is processed asynchronously from the time you submit the command. (To process the command synchronously with other IBM MQ commands use the WAIT(YES) option with QUIESCE, but be aware that the z/OS console is locked from IBM MQ command input for the entire QUIESCE period.)

During the quiesce period:

- Jobs and users on the queue manager are allowed to go through commit processing, but are suspended if they try to update any IBM MQ resource after the commit.
- Jobs and users that only read data can be affected, since they might be waiting for locks held by jobs or users that were suspended.
- New tasks can start, but they cannot update data.

The output from the DISPLAY LOG command uses the message CSQV400I to indicate that a quiesce is in effect. For example:

```
CSQJ322I +CSQ1 DISPLAY LOG report ...
Parameter   Initial value         SET value
----------- --------------------- ---------------------
INBUFF      60
OUTBUFF     4000
MAXRTU      2
MAXARCH     2
TWOACTV     YES
TWOARCH     YES
TWOBSDS     YES
OFFLOAD     YES
WRTHRSH     20
DEALLCT     0
End of LOG report
CSQJ370I +CSQ1 LOG status report ...
Copy %Full DSName
1      68  VICY.CSQ1.LOGCOPY1.DS01
2      68  VICY.CSQ1.LOGCOPY2.DS01
Restarted at 2014-04-15 09:49:30 using RBA=000000000891B000
Latest RBA=000000000891CCF8
Offload task is AVAILABLE
Full logs to offload - 0 of 4
CSQV400I +CSQ1 ARCHIVE LOG QUIESCE CURRENTLY ACTIVE
CSQ9022I +CSQ1 CSQJC001 ' DISPLAY LOG' NORMAL COMPLETION
```

When all updates are quiesced, the quiesce history record in the BSDS is updated with the date and time that the active log data sets were truncated, and with the last-written RBA in the current active log data sets. IBM MQ truncates the current active log data sets, switches to the next available active log data sets, and issues message CSQJ311I stating that the offload process started.

If updates cannot be quiesced before the quiesce period expires, IBM MQ issues message CSQJ317I, and ARCHIVE LOG processing terminates. The current active log data sets are not truncated, nor switched to the next available log data sets, and the offload process is not started.

Whether the quiesce was successful or not, all suspended users and jobs are then resumed, and IBM MQ issues message CSQJ312I, stating that the quiesce is ended and update activity is resumed.

If ARCHIVE LOG is issued when the current active log is the last available active log data set, the command is not processed, and IBM MQ issues the following message:

```
CSQJ319I - csect-name CURRENT ACTIVE LOG DATA SET IS THE LAST
AVAILABLE ACTIVE LOG DATA SET. ARCHIVE LOG PROCESSING
WILL BE TERMINATED
```

If ARCHIVE LOG is issued when another ARCHIVE LOG command is already in progress, the new command is not processed, and IBM MQ issues the following message:

```
CSQJ318I - ARCHIVE LOG COMMAND ALREADY IN PROGRESS
```

For information about the messages issued during archiving, see Messages for IBM MQ for z/OS.

Restarting the log archive process after a failure

If there is a problem during the log archive process (for example, a problem with allocation or tape mounts), the archiving of the active log might be suspended. You can cancel the archive process and restart it by using the ARCHIVE LOG CANCEL OFFLOAD command. This command cancels any offload processing currently in progress, and restarts the archive process. It starts with the oldest log data set that has not been archived, and proceeds through all active log data sets that need offloading. Any log archive operations that have been suspended are restarted.

Use this command only if you are sure that the current log archive task is no longer functioning, or if you want to restart a previous attempt that failed. This is because the command might cause an abnormal termination of the offload task, which might result in a dump.

Controlling archiving and logging:

You can control compression, printing, archiving, recovery and logging with using the CSQ6LOGP, CSQ6ARVP, and CSQ6SYSP macros.

Many aspects of archiving and logging are controlled by parameters set using the CSQ6LOGP, CSQ6ARVP and CSQ6SYSP macros of the system parameter module when the queue manager is customized. See Task 17: Tailor your system parameter module for details of these macros.

Some of these parameters can be changed while a queue manager is running using the IBM MQ MQSC SET LOG, SET SYSTEM and SET ARCHIVE commands. They are shown in Table 14:

Table 14. Archiving and logging parameters that can be changed while a queue manager is running

SET command	Parameters
LOG	WRTHRSH, MAXARCH, DEALLCT, MAXRTU, COMPLOG
ARCHIVE	All
SYSTEM	LOGLOAD

You can display the settings of all the parameters using the MQSC DISPLAY LOG, DISPLAY ARCHIVE and DISPLAY SYSTEM commands. These commands also show status information about archiving and logging.

Controlling log compression

You can enable and disable the compression of log records using either

- The SET and DISPLAY LOG commands in MQSC; see The MQSC commands
- Invoking PCF interface. See “Introduction to Programmable Command Formats” on page 6
- Using the CSQ6LOGP macro in the system parameter module; see Using CSQ6LOGP

Printing log records

You can extract and print log records using the CSQ1LOGP utility. For instructions, see The log print utility.

Recovering logs

Normally, you do not need to back up and restore the IBM MQ logs, especially if you are using dual logging. However, in rare circumstances, such as an I/O error on a log, you might need to recover the logs. Use Access Method Services to delete and redefine the data set, and then copy the corresponding dual log into it. For more information see Using Access Method Services.

Discarding archive log data sets:

You can discard your archive log data sets and choose to discard the logs automatically or manually.

You must keep enough log data to be able to perform unit of work recovery, page set media recovery if a page set is lost, or CF structure media recovery if a CF structure is lost. Do not discard archive log data sets that might be required for recovery; if you discard these archive log data sets you might not be able to perform required recovery operations.

If you have confirmed that your archive log data sets can be discarded, you can do this in either of the following ways:
- Automatic archive log data set deletion
- Manually deleting archive log data sets

Automatic archive log data set deletion

You can use a DASD or tape management system to delete archive log data sets automatically. The retention period for IBM MQ archive log data sets is specified by the retention period field ARCRETN in the CSQ6ARVP installation macro (see the Using CSQ6ARVP for more information).

The default for the retention period specifies that archive logs are to be kept for 9999 days (the maximum). **You can change the retention period but you must ensure that you can accommodate the number of backup cycles that you have planned for**.

IBM MQ uses the retention period value as the value for the JCL parameter RETPD when archive log data sets are created.

The retention period set by the MVS™/DFP storage management subsystem (SMS) can be overridden by this IBM MQ parameter. Typically, the retention period is set to the smaller value specified by either IBM MQ or SMS. The storage administrator and IBM MQ administrator must agree on a retention period value that is appropriate for IBM MQ.

Note: IBM MQ does not have an automated method to delete information about archive log data sets from the BSDS, because some tape management systems provide external manual overrides of retention periods. Therefore, information about an archive log data set can still be in the BSDS long after the data set retention period has expired and the data set has been scratched by the tape management system. Conversely, the maximum number of archive log data sets might have been exceeded and the data from the BSDS might have been dropped before the data set has reached its expiration date.

If archive log data sets are deleted automatically, remember that the operation does not update the list of archive logs in the BSDS. You can update the BSDS with the change log inventory utility, as described in “Changing the BSDS” on page 311. The update is not essential. Recording old archive logs wastes space in the BSDS, but does no other harm.

Manually deleting archive log data sets

You must keep all the log records as far back as the lowest RBA identified in messages CSQI024I and CSQI025I. This RBA is obtained using the DISPLAY USAGE command that you issued when creating a point of recovery using Method 1: Full backup.

Read Creating a point of recovery for non-shared resources before discarding any logs.

Locate and discard archive log data sets

Having established the minimum log RBA required for recovery, you can find archive log data sets that contain only earlier log records by performing the following procedure:

1. Use the print log map utility to print the contents of the BSDS. For an example of the output, see The print log map utility.
2. Find the sections of the output titled "ARCHIVE LOG COPY n DATA SETS". If you use dual logging, there are two sections. The columns labeled STARTRBA and ENDRBA show the range of RBAs contained in each volume. Find the volumes with ranges that include the minimum RBA you found with messages CSQI024I and CSQI025I. These are the earliest volumes you need to keep. If you are using dual-logging, there are two such volumes.

   If no volumes have an appropriate range, one of the following cases applies:

   - The minimum RBA has not yet been archived, and you can discard all archive log volumes.
   - The list of archive log volumes in the BSDS wrapped around when the number of volumes exceeded the number allowed by the MAXARCH parameter of the CSQ6LOGP macro. If the BSDS does not register an archive log volume, that volume cannot be used for recovery. Therefore, consider adding information about existing volumes to the BSDS. For instructions, see “Changes for archive logs” on page 313.

     Also consider increasing the value of MAXARCH. For information, see the Using CSQ6LOGP.
3. Delete any archive log data set or volume with an ENDRBA value that is less than the STARTRBA value of the earliest volume you want to keep. If you are using dual logging, delete both such copies.

   Because BSDS entries wrap around, the first few entries in the BSDS archive log section might be more recent than the entries at the bottom. Look at the combination of date and time and compare their ages. Do not assume that you can discard all entries *above* the entry for the archive log containing the minimum LOGRBA.

   Delete the data sets. If the archives are on tape, erase the tapes. If they are on DASD, run a z/OS utility to delete each data set. Then, if you want the BSDS to list only existing archive volumes, use the change log inventory utility (CSQJU003) to delete entries for the discarded volumes. See “Changes for archive logs” on page 313 for an example.

The effect of log shunting:

Long running transactions can cause unit of work log records which span log data sets. IBM MQ handles this scenario by using log shunting, a technique which moves the log records to optimize the quantity of log data retained, and queue manager restart time.

When a unit of work is considered to be long, a representation of each log record is written further down the log. This is known as *log shunting*. It is described more fully in Log files.

The queue manager uses these shunted log records instead of the originals after a failure, to ensure unit of work integrity. There are two benefits to this:

- the quantity of log data which must be retained for unit of work coordination is reduced
- less log data must be traversed at queue manager restart time, so the queue manager is restarted more quickly

Shunted log records do not contain sufficient information for media recovery operations.

Data held in the log is used for two distinct purposes; media recovery and unit of work coordination. If a media failure occurs which affects either a CF structure or page set, the queue manager can recover the media to the point of failure by restoring a prior copy and updating this using data contained in the log. Persistent activity performed in a unit of work is recorded on the log so that in the event of a failure, it can either be backed out or locks can be recovered on changed resources. The quantity of log data you need to retain to enable queue manager recovery is affected by these two elements.

For media recovery, you must retain sufficient log data to be able to perform media recovery from at least the most recent media copy and to be able to back out. (Your site may stipulate the ability to recover from older backups.) For unit of work integrity, you must retain the log data for your oldest in flight or indoubt units of work.

To assist you with managing the system, the queue manager detects old units of work at each log archive and reports them in messages CSQJ160 and CSQJ161. An internal task reads unit of work log information for these old units of work and rewrites it in a more succinct form to the current position in the log. Message CSQR026 indicates when this has happened. The MQSC command DISPLAY USAGE TYPE(DATASET) can also help you to manage the retention of log data. The command reports 3 pieces of recovery information:

1. how much of the log must be retained for unit of work recovery
2. how much of the log must be retained for media recovery of page sets
3. for a queue manager in a queue-sharing group, how much of the log must be retained for media recovery of CF structures

For each of these, an attempt is made to map the oldest log data required into a data set. As new units of work start and stop, we would expect (1) above to move to a more recent position in the log. If it is not moving, the long running UOW messages warn you that there is an issue. (2) relates to page set media recovery if the queue manager were to be shut down now and restarted. It does not know about when you last backed up your page sets, or which backup you might have to use if there was a page set failure. It normally moves to a more recent position in the log during checkpoint processing as changes held in the buffer pools are written to the page sets. In (3), the queue manager does know about CF structure backups taken either on this queue manager or on other queue managers in the queue sharing group. However, CF structure recovery requires a merge of log data from all queue managers in the queue-sharing group which have interacted with the CF structure since the last backup. This means that the log data is identified by a log record sequence number, (or LRSN), which is timestamp based and so applicable across the entire queue-sharing group rather than an RBA which would be different on different queue managers in the queue-sharing group. It normally moves to a more recent position in the log as BACKUP CFSTRUCT commands are performed on either this or other queue managers in the queue-sharing group.

Resetting the queue manager's log:

Use this topic to understand how to reset the queue manager's log.

You must not allow the queue manager log RBA to wrap around from the end of the log RBA range to 0, as this leads to a queue manager outage and all persistent data will become unrecoverable. The end of the log RBA is either a value of FFFFFFFFFFFF (if 6-byte RBAs as in use), or FFFFFFFFFFFFFFFF (if 8-byte RBAs are in use).

The queue manager issues messages CSQI045I, CSQI046E, CSQI047E, and CSQJ032E to indicate that the used log range is significant and that you should plan to take action to avoid an unplanned outage.

The queue manager terminates with reason code 00D10257 when the RBA value reaches FFF800000000 (if 6-byte log RBAs are in use) or FFFFFFC000000000 (if 8-byte log RBAs are in use).

If 6-byte log RBAs are in use, consider converting the queue manager to use 8-byte log RBAs rather than resetting the queue manager's log, following the process described in Implementing the larger log Relative Byte Address. Converting a queue manager to use 8-byte log RBAs requires a shorter outage than resetting the log, and increases the period of time before you have to reset the log.

Message CSQJ034I, issued during queue manager initialization, indicates the end of the log RBA range for the queue manager as configured, and can be used to determine whether 6-byte or 8-byte log RBAs are in use.

The procedure to follow to reset the queue manager's log is as follows:

1. Resolve any unresolved units of work. The number of unresolved units of work is displayed at queue manager startup in message CSQR005I as the INDOUBT count. At each checkpoint, and at queue manager shutdown, the queue manager automatically issues the command

   `DISPLAY CONN(*) TYPE(CONN) ALL WHERE(UOWSTATE EQ UNRESOLVED)` to provide information about unresolved units of work.

   See How in-doubt units of recovery are resolved for information on resolving units of recovery. The ultimate recourse is to use the `RESOLVE INDOUBT` MQSC command to manually resolve indoubt units of recovery.
2. Shutdown the queue manager cleanly.

   You can use either `STOP QMGR` or `STOP QMGR MODE(FORCE)` as both these commands flush any changed pages from bufferpools to the pagesets.
3. If a queue manager is part of a queue sharing group, take CFSTRUCT backups on other queue managers for all structures in the queue sharing group. This ensures that the most recent backups are not in this queue manager's log, and that this queue manager's log is not required for CFSTRUCT recovery.
4. Define new logs and BSDS using CSQJU003 (see The change log inventory utility for more information on using the change log inventory utility).
5. Run `CSQUTIL RESETPAGE` against all the page sets for this queue manager (see Copying a page and resetting the log for more information on using this function). Note that page set RBAs can be reset independently, so multiple concurrent jobs (for example, one per page set) can be submitted to reduce the elapsed time for this step.
6. Restart the queue manager

Related concepts:

../com.ibm.mq.adm.doc/q119810_.dita
Previous releases of IBM MQ for z/OS used a 6-byte log RBA to identify the location of data within the log. In IBM MQ Version 8.0, the log RBA can be 8 bytes long, increasing the period of time before you have to reset the log.

Implementing the larger log Relative Byte Address:

Previous releases of IBM MQ for z/OS used a 6-byte log RBA to identify the location of data within the log. In IBM MQ Version 8.0, the log RBA can be 8 bytes long, increasing the period of time before you have to reset the log.

This new feature needs to be explicitly enabled. See Planning to increase the maximum addressable log range for considerations when planning to enable 8 byte log RBA.

Perform these instructions, in the order shown, to enable 8 byte log RBA on a single IBM MQ for z/OS queue manager:

1. Enable IBM MQ Version 8.0 new functions using OPMODE.

   For queue managers in a queue-sharing group, you do not need to take a total queue-sharing group outage. You can stop each queue manager in turn, enable it for OPMODE=(NEWFUNC,800) and restart it.

   Once all queue managers in the queue sharing group are running with OPMODE(NEWFUNC,800), perform the following steps for each queue manager in the queue-sharing group until all queue managers are running with the new BSDS.

2. Allocate new BSDS data sets with similar attributes to the current BSDS. You can tailor sample CSQ4BSDS and delete any irrelevant statement, or you can use your existing JCL, but change the BSDS name to something like `++HLQ++.NEW.BSDS01`.

   Notes:

   a. Check the attributes of your new BSDS. The only attribute that might change is the size of the BSDS.
   b. The new BSDS contains more data that the current BSDS, therefore, you must ensure that the new data sets are allocated with sufficient available space. See Planning your logging environment, and the associated topics, for the recommended values when defining a new BSDS.
3. Shut down the queue manager cleanly.
4. Run the BSDS conversion utility (CSQJUCNV) to convert the existing BSDS to the new BSDS data sets. This usually takes a few seconds to run.

   Your existing BSDS will not be changed during this process, and you can use that for the initialization of the queue manager in the case of an unsuccessful conversion.
5. Rename the current BSDS to become the old BSDS, and the new BSDS to become the current BSDS, so that the new data sets are used when you next restart the queue manager. You can use the DFSMS Access Method Services ALTER command, for example:
   ```
   ALTER '++HLQ++.BSDS01' NEWNAME('++HLQ++.OLD.BSDS01')
   ALTER '++HLQ++.NEW.BSDS01' NEWNAME('++HLQ++.BSDS01')
   ```
   Ensure that you also issue commands to rename both the data and index portions of the VSAM cluster.
6. Restart the queue manager. It should start in the same amount of time as it would have done when using 6 byte log RBA.

   If the queue manager does not restart successfully due to a failure to access the converted BSDS, attempt to identify the cause of the failure, resolve the problem and retry the operation. If required, contact your IBM support center for assistance.

   If necessary, the change can be backed out at this point by:
   a. Renaming the current BSDS to become the new BSDS.
   b. Renaming the old BSDS to become the current BSDS.
   c. Restarting the queue manager.

   Once the queue manager has been successfully restarted with the converted BSDS, do not attempt to start the queue manager using the old BSDS.
7. Message CSQJ034I is issued during queue manager initialization to indicate the end of the log RBA for the queue manager as configured. Confirm that the end of the log RBA range displayed is FFFFFFFFFFFFFFFF. This indicates that 8 byte log RBA is in use.

Note: In order to enable an 8 byte log RBA on a new IBM MQ Version 8.0 queue manager, before it is first started, you must first create an empty version 1 format BSDS and use that as input to the BSDS conversion utility to produce a version 2 format BSDS. See Create the bootstrap and log datasets for information on how you carry out this process.

Larger log Relative Byte Address

The BSDS conversion utility (CSQJUCNV)

Managing the bootstrap data set (BSDS)

The bootstrap data set (BSDS) is used to reference log data sets, and log records. Use this topic to understand how you can examine, change, and recover the BSDS.

For more information, see The bootstrap data set.

This topic describes the tasks involved in managing the bootstrap data set. It contains these sections:
- "Finding out what the BSDS contains"
- "Changing the BSDS" on page 311
- "Recovering the BSDS" on page 315

Finding out what the BSDS contains:

You can use the print log map utility (CSQJU004) to examine the contents of the BSDS.

The print log map utility (CSQJU004) is a batch utility that lists the information stored in the BSDS. For instructions on running it, see The print log map utility.

The BSDS contains:
- Time stamps
- Active log data set status

Time stamps in the BSDS

The output of the print log map utility shows the time stamps, which are used to record the date and time of various system events, that are stored in the BSDS.

The following time stamps are included in the header section of the report:

SYSTEM TIMESTAMP

Reflects the date and time the BSDS was last updated. The BSDS time stamp can be updated when:
- The queue manager starts.
- The write threshold is reached during log write activities. Depending on the number of output buffers you have specified and the system activity rate, the BSDS might be updated several times a second, or might not be updated for several seconds, minutes, or even hours. For details of the write threshold, see the WRTHRSH parameter of the CSQ6LOGP macro in Using CSQ6LOGP.
- IBM MQ drops into a single BSDS mode from its normal dual BSDS mode due to an error. This can occur when a request to get, insert, point to, update, or delete a BSDS record is unsuccessful. When this error occurs, IBM MQ updates the time stamp in the remaining BSDS to force a time stamp mismatch with the disabled BSDS.

UTILITY TIMESTAMP

The date and time the contents of the BSDS were altered by the change log inventory utility (CSQJU003).

The following time stamps are included in the active and archive log data sets portion of the report:

Active log date
The date the active log entry was created in the BSDS, that is, when the CSQJU003 NEWLOG was done.

Active log time
The time the active log entry was created in the BSDS, that is, when the CSQJU003 NEWLOG was done.

Archive log date
The date the archive log entry was created in the BSDS, that is, when the CSQJU003 NEWLOG was done or the archive itself was done.

Archive log time
The time the archive log entry was created in the BSDS, that is, when the CSQJU003 NEWLOG was done or the archive itself was done.

Active log data set status

The BSDS records the status of an active log data set as one of the following:

NEW The data set has been defined but never used by IBM MQ, or the log was truncated to a point before the data set was first used. In either case, the data set starting and ending RBA values are reset to zero.

REUSABLE
Either the data set has been defined but never used by IBM MQ, or the data set has been offloaded. In the print log map output, the start RBA value for the last REUSABLE data set is equal to the start RBA value of the last archive log data set.

NOT REUSABLE
The data set contains records that have not been offloaded.

STOPPED
The offload processor encountered an error while reading a record, and that record could not be obtained from the other copy of the active log.

TRUNCATED
Either:

- An I/O error occurred, and IBM MQ has stopped writing to this data set. The active log data set is offloaded, beginning with the starting RBA and continuing up to the last valid record segment in the truncated active log data set. The RBA of the last valid record segment is lower than the ending RBA of the active log data set. Logging is switched to the next available active log data set, and continues uninterrupted.

or

- An ARCHIVE LOG function has been called, which has truncated the active log.

The status appears in the output from the print log map utility.

Changing the BSDS:

You do not have to take special steps to keep the BSDS updated with records of logging events because IBM MQ does that automatically.

However, you might want to change the BSDS if you do any of the following:
- Add more active log data sets.
- Copy active log data sets to newly allocated data sets, for example, when providing larger active log allocations.
- Move log data sets to other devices.
- Recover a damaged BSDS.
- Discard outdated archive log data sets.

You can change the BSDS by running the change log inventory utility (CSQJU003). Only run this utility when the queue manager is inactive, or you might get inconsistent results. The action of the utility is controlled by statements in the SYSIN data set. This section shows several examples. For complete instructions, see The change log inventory utility.

You can copy an active log data set only when the queue manager is inactive because IBM MQ allocates the active log data sets as exclusive (DISP=OLD) at queue manager startup.

Changes for active logs:

Use this topic to understand how you can change the active logs using the BSDS.

You can add to, delete from, and record entries in the BSDS for active logs using the change log utility. Examples only are shown here; replace the data set names shown with the ones you want to use. For more details of the utility, see The change log inventory utility.

See these sections for more information:
- Adding record entries to the BSDS
- Deleting information about the active log data set from the BSDS
- Recording information about the log data set in the BSDS
- Increasing the size of the active log
- The use of CSQJUFMT

Adding record entries to the BSDS

If an active log has been flagged as "stopped", it is not reused for logging; however, it continues to be used for reading. Use the access method services to define new active log data sets, then use the change log inventory utility to register the new data sets in the BSDS. For example, use:

```
NEWLOG DSNAME=MQM111.LOGCOPY1.DS10,COPY1
NEWLOG DSNAME=MQM111.LOGCOPY2.DS10,COPY2
```

If you are copying the contents of an old active log data set to the new one, you can also give the RBA range and the starting and ending time stamps on the NEWLOG function.

Deleting information about the active log data set from the BSDS

To delete information about an active log data set from the BSDS, you could use:

```
DELETE DSNAME=MQM111.LOGCOPY1.DS99
DELETE DSNAME=MQM111.LOGCOPY2.DS99
```

Recording information about the log data set in the BSDS

To record information about an existing active log data set in the BSDS, use:

```
NEWLOG DSNAME=MQM111.LOGCOPY1.DS10,COPY2,STARTIME=19930212205198,
ENDTIME=19930412205200,STARTRBA=6400,ENDRBA=94FF
```

You might need to insert a record containing this type of information in the BSDS because:

- The entry for the data set has been deleted, but is needed again.
- You are copying the contents of one active log data set to another data set.
- You are recovering the BSDS from a backup copy.

Increasing the size of the active log

There are two methods of achieving this process.

1. When the queue manager is active:
   a. Define new larger log data sets using JCL.
   b. Add the new log data sets to the active queue manager using the MQSC DEFINE LOG command.
   c. Use the MQSC ARCHIVE LOG command to move the current active log, to be a new larger log.
   d. Wait for the archive of the smaller active log dataset to complete.
   e. Shutdown the queue manager, using the CSQJU003 utility to remove the old small active logs.
   f. Restart the queue manager.
2. When the queue manager is inactive:
   a. Stop the queue manager. This step is required because IBM MQ allocates all active log data sets for its exclusive use when it is active.
   b. Use Access Method Services ALTER with the NEWNAME option to rename your active log data sets.
   c. Use Access Method Services DEFINE to define larger active log data sets.

      By reusing the old data set names, you do not have to run the change log inventory utility to establish new names in the BSDSs. The old data set names and the correct RBA ranges are already in the BSDSs.
   d. Use Access Method Services REPRO to copy the old (renamed) data sets into their appropriate new data sets.

      Note: This step can take a long time, so your enterprise could be out of action for this period.
   e. Start the queue manager.

If all your log data sets are the same size, your system will be operationally more consistent and efficient. If the log data sets are not the same size, it is more difficult to track your system's logs, and so space can be wasted.

The use of CSQJUFMT

Do not run a CSQJUFMT format when increasing the size of an active log.

If you run CSQJUFMT (in order to provide a performance advantage the first time the queue manager writes to the new active log) you receive messages:

```
IEC070I 203-204,XS95GTLX,REPRO02,OUTPUT,B857,SPMG02, 358
IEC070I MG.W.MG4E.LOGCOPY1.DS02,MG.W.MG4E.LOGCOPY1.DS02.DATA,
IDC3302I ACTION ERROR ON MG.W.MG4E.LOGCOPY1.DS02
IDC3351I ** VSAM I/O RETURN CODE IS 28 - RPLFDBWD = X'2908001C'
IDC31467I MAXIMUM ERROR LIMIT REACHED.

IDC0005I NUMBER OF RECORDS PROCESSED WAS 0
```

In addition, if you use the Access Method Services REPRO, ensure that you define a new empty log.

If you use REPRO to copy the old (renamed) data set into its respective new data set, the default is NOREPLACE.

This means that REPRO does not replace a record that is already on the designated data set. When formatting is done on the data set, the RBA value is reset. The net result is a data set that is not empty after formatting.

Changes for archive logs:

Use this topic to understand how to change the archive logs.

You can add to, delete from, and change the password of, entries in the BSDS for archive logs. Examples only are shown here; replace the data set names shown with the ones you want to use. For more details of the utility, see The change log inventory utility.

- Adding an archive log
- Deleting an archive log
- Changing the password of an archive log

Adding an archive log

When the recovery of an object depends on reading an existing archive log data set, the BSDS must contain information about that data set so that IBM MQ can find it. To register information about an existing archive log data set in the BSDS, use:

```
NEWLOG DSNAME=CSQARC1.ARCHLOG1.E00021.T2205197.A0000015,COPY1VOL=CSQV04,
UNIT=TAPE,STARTRBA=3A190000,ENDRBA=3A1F0FFF,CATALOG=NO
```

Deleting an archive log

To delete an entire archive log data set on one or more volumes, use:

```
DELETE DSNAME=CSQARC1.ARCHLOG1.E00021.T2205197.A0000015,COPY1VOL=CSQV04
```

Changing the password of an archive log

If you change the password of an existing archive log data set, you must also change the information in the BSDS.

1. List the BSDS, using the print log map utility.
2. Delete the entry for the archive log data set with the changed password, using the DELETE function of the CSQJU003 utility (see topic The change log inventory utility).
3. Name the data set as for a new archive log data set. Use the NEWLOG function of the CSQJU003 utility (see topic The change log inventory utility), and give the new password,

the starting and ending RBAs, and the volume serial numbers (which can be found in the print log map utility output, see The print log map utility).

To change the password for new archive log data sets, use:

```
ARCHIVE PASSWORD= password
```

To stop placing passwords on new archive log data sets, use:

```
ARCHIVE NOPASSWD
```

Note: Only use the ARCHIVE utility function if you do not have an external security manager.

Changing the high-level qualifier (HLQ) for the logs and BSDS:

Use this topic to understand the procedure required to change the high-level qualifier (HLQ).

Before you begin

You must end the queue manager normally before copying any of the logs or data sets to the new data sets. This is to ensure that the data is consistent and no recovery is needed during restart.

About this task

This task provides information about how to change the HLQ for the logs and BSDS. To do this, follow these steps:

Procedure

1. Run the log print utility CSQJU004 to record the log data set information. This information is needed later.
2. You can either:
   a. run DSS backup and restore with rename on the log and BSDS data sets to be renamed, or
   b. use AMS DEFINE and REPRO to create the HLQ data sets and copy the data from the old data sets.
3. Modify the MSTR and CHIN procedures to point to the new data sets.
4. Delete the old log information in the new copy of the BSDS using CSQJU003.
5. Define the new log data sets to the new BSDS using the NEWLOG function of CSQJU003. Keep all information about each log the same, apart from the HLQ.
6. The new BSDS should reflect the same information that was recorded for the old logs in the old BSDS. The HLQ should be the only thing that has changed.

What to do next

Compare the CSQJU004 output for the old and new BSDS to ensure that they look EXACTLY the same (except for the HLQs) before starting the queue manager.

Note: Care must be taken when performing these operations. Incorrect actions might lead to unrecoverable situations. Check the PRINT LOG MAP UTILITY output and make sure that all the information needed for recovery or restart has been included.

Recovering the BSDS:

If IBM MQ is operating in dual BSDS mode and one BSDS becomes damaged, forcing IBM MQ into single BSDS mode, IBM MQ continues to operate without a problem (until the next restart).

To return the environment to dual BSDS mode:

1. Use Access Method Services to rename or delete the damaged BSDS and to define a new BSDS with the same name as the damaged BSDS. Example control statements can be found in job CSQ4BREC in thlqual.SCSQPROC.
2. Issue the IBM MQ command RECOVER BSDS to make a copy of the valid BSDS in the newly allocated data set and to reinstate dual BSDS mode.

If IBM MQ is operating in single BSDS mode and the BSDS is damaged, or if IBM MQ is operating in dual BSDS mode and both BSDSs are damaged, the queue manager stops and does not restart until the BSDS data sets are repaired. In this case:

1. Locate the BSDS associated with the most recent archive log data set. The data set name of the most recent archive log appears on the job log in the last occurrence of message CSQJ003I, which indicates that offload processing has been completed successfully. In preparation for the rest of this procedure, it is a good practice to keep a log of all successful archives noted by that message:
   - If archive logs are on DASD, the BSDS is allocated on any available DASD. The BSDS name is like the corresponding archive log data set name; change only the first letter of the last qualifier, from A to B, as in this example:

     Archive log name
     CSQ.ARCHLOG1. ***A*** 0000001

     BSDS copy name
     CSQ.ARCHLOG1. ***B*** 0000001
   - If archive logs are on tape, the BSDS is the first data set of the first archive log volume. The BSDS is not repeated on later volumes.
2. If the most recent archive log data set has no copy of the BSDS (for example, because an error occurred when offloading it), locate an earlier copy of the BSDS from earlier offload processing.
3. Rename *damaged* BSDSs using the Access Method Services ALTER command with the NEWNAME option. If you want to delete a damaged BSDS, use the Access Method Services DELETE command. For each damaged BSDS, use Access Method Services to define a new BSDS as a replacement data set. Job CSQ4BREC in thlqual.SCSQPROC contains Access Method Services control statements to define a new BSDS.
4. Use the Access Method Services REPRO command to copy the BSDS from the archive log to one of the replacement BSDSs you defined in step 3. Do not copy any data to the second replacement BSDS, you do that in step 5 on page 316.
   a. Print the contents of the replacement BSDS.

      Use the print log map utility (CSQJU004) to print the contents of the replacement BSDS. This enables you to review the contents of the replacement BSDS before continuing your recovery work.
   b. Update the archive log data set inventory in the replacement BSDS.

      Examine the output from the print log map utility and check that the replacement BSDS does not contain a record of the archive log from which the BSDS was copied. If the replacement BSDS is an old copy, its inventory might not contain all archive log data sets that were created more recently. The BSDS inventory of the archive log data sets must be updated to reflect the current subsystem inventory.

      Use the change log inventory utility (CSQJU003) NEWLOG statement to update the replacement BSDS, adding a record of the archive log from which the BSDS was copied. If the archive log data set is password-protected, use the PASSWORD option of the NEWLOG function. Also, if the archive log data set is cataloged, ensure that the CATALOG option of the NEWLOG function is properly set to CATALOG=YES. Use the NEWLOG statement to add any additional archive log data sets that were created later than the BSDS copy.

c. Update passwords in the replacement BSDS.

   The BSDS contains passwords for the archive log data sets and for the active log data sets. To ensure that the passwords in the replacement BSDS reflect the current passwords used by your installation, use the change log inventory ARCHIVE utility function with the PASSWORD option.

d. Update the active log data set inventory in the replacement BSDS.

   In unusual circumstances, your installation might have added, deleted, or renamed active log data sets since the BSDS was copied. In this case, the replacement BSDS does not reflect the actual number or names of the active log data sets your installation currently has in use.

   If you need to delete an active log data set from the replacement BSDS log inventory, use the change log inventory utility DELETE function.

   If you need to add an active log data set to the replacement BSDS log inventory, use the change log inventory utility NEWLOG function. Ensure that the RBA range is specified correctly on the NEWLOG function. If the active log data set is password-protected, use the PASSWORD option.

   If you need to rename an active log data set in the replacement BSDS log inventory, use the change log inventory utility DELETE function, followed by the NEWLOG function. Ensure that the RBA range is specified correctly on the NEWLOG function. If the active log data set is password-protected, use the PASSWORD option.

e. Update the active log RBA ranges in the replacement BSDS.

   Later, when the queue manager restarts, it compares the RBAs of the active log data sets listed in the BSDS with the RBAs found in the actual active log data sets. If the RBAs do not agree, the queue manager does not restart. The problem is magnified when an old copy of the BSDS is used. To solve this problem, use the change log inventory utility (CSQJU003) to adjust the RBAs found in the BSDS using the RBAs in the actual active log data sets. You do this by:

   - Using the print log records utility (CSQ1LOGP) to print a summary report of the active log data set. This shows the starting and ending RBAs.
   - Comparing the actual RBA ranges with the RBA ranges you have just printed, when the RBAs of all active log data sets are known.

     If the RBA ranges are equal for all active log data sets, you can proceed to the next recovery step without any additional work.

     If the RBA ranges are not equal, adjust the values in the BSDS to reflect the actual values. For each active log data set that needs to have the RBA range adjusted, use the change log inventory utility DELETE function to delete the active log data set from the inventory in the replacement BSDS. Then use the NEWLOG function to redefine the active log data set to the BSDS. If the active log data sets are password-protected, use the PASSWORD option of the NEWLOG function.

f. If only two active log data sets are specified for each copy of the active log, IBM MQ can have difficulty during queue manager restart. The problem can arise when one of the active log data sets is full and has not been offloaded, while the second active log data set is close to filling. In this case, add a new active log data set for each copy of the active log and define each new active log data set in the replacement BSDS log inventory.

   Use the Access Method Services DEFINE command to define a new active log data set for each copy of the active log and use the change log inventory utility NEWLOG function to define the new active log data sets in the replacement BSDS. You do not need to specify the RBA ranges on the NEWLOG statement. However, if the active log data sets are password-protected, use the PASSWORD option of the NEWLOG function. Example control statements to accomplish this task can be found in job CSQ4LREC in thlqual.SCSQPROC.

5. Copy the updated BSDS to the second new BSDS data set. The BSDSs are now identical.

   Use the print log map utility (CSQJU004) to print the contents of the second replacement BSDS at this point.

6. See Active log problems for information about what to do if you have lost your current active log data set.
7. Restart the queue manager using the newly constructed BSDS. IBM MQ determines the current RBA and what active logs need to be archived.

Managing page sets

Use this topic to understand how to manage the page sets associated with a queue manager.

This topic describes how to add, copy, and generally manage the page sets associated with a queue manager. It contains these sections:
- "How to change the high-level qualifier (HLQ) for the page sets"
- "How to add a page set to a queue manager"
- "What to do when one of your page sets becomes full" on page 318
- "How to balance loads on page sets" on page 318
- How to increase the size of a page set
- "How to reduce a page set" on page 322
- "How to reintroduce a page set" on page 322
- "How to back up and recover page sets" on page 323
- "How to delete page sets" on page 327
- "How to back up and restore queues using CSQUTIL" on page 327

See Page sets for a description of page sets, storage classes, buffers, and buffer pools, and some of the performance considerations that apply.

How to change the high-level qualifier (HLQ) for the page sets

This task gives information on how to change the HLQ for the page sets. To perform this task, do the following:
1. Define the new HLQ page sets.
2. If the size allocation is the same as the old page sets, copy the existing page set using REPRO to the empty new HLQ page sets. If you are increasing the size of the page sets, use the FORMAT function of CSQUTIL to format the destination page set. For more information, see Formatting page sets (FORMAT).
3. Use the COPYPAGE function of CSQUTIL to copy all the messages from the source page set to the destination page set. For more information, see Expanding a page set (COPYPAGE).
4. Change the CSQP00xx DD statement in the queue manager procedure to point to the new HLQ page sets.

Restart the queue manager and verify the changes to the page sets.

How to add a page set to a queue manager

This description assumes that you have a queue manager that is already running. You might need to add a page set if, for example, your queue manager has to cope with new applications using new queues.

To add a new page set, use the following procedure:
1. Define and format the new page set. You can use the sample JCL in thlqual.SCSQPROC(CSQ4PAGE) as a basis. For more information, see Formatting page sets (FORMAT).

   Take care not to format any page sets that are in use, unless this is what you intend. If so, use the FORCE option of the FORMAT utility function.
2. Use the DEFINE PSID command with the DSN option to associate the page set with a buffer pool.

3. Add the appropriate storage class definitions for your page set by issuing DEFINE STGCLASS commands.
4. Optionally, to document how your queue manager is configured:
   a. Add the new page set to the started task procedure for your queue manager.
   b. Add a definition for the new page set to your CSQINP1 initialization data set.
   c. Add a definition for the new storage class to your CSQ4INYR initialization data set member.

For details of the DEFINE PSID and DEFINE STGCLASS commands, see DEFINE PSID and DEFINE STGCLASS.

What to do when one of your page sets becomes full

You can find out about the utilization of page sets by using the IBM MQ command DISPLAY USAGE. For example, the command:

```
DISPLAY USAGE PSID(03)
```

displays the current state of the page set 03. This tells you how many free pages this page set has.

If you have defined secondary extents for your page sets, they are dynamically expanded each time they fill up. Eventually, all secondary extents are used, or no further disk space is available. If this happens, an application receives the return code MQRC_STORAGE_MEDIUM_FULL.

If an application receives a return code of MQRC_STORAGE_MEDIUM_FULL from an MQI call, this is a clear indication that there is not enough space left on the page set. If the problem persists or is likely to recur, you must do something to solve it.

You can approach this problem in a number of ways:
- Balance the load between page sets by moving queues from one page set to another.
- Expand the page set. See “How to increase the size of a page set” on page 320 for instructions.
- Redefine the page set so that it can expand beyond 4 GB to a maximum size of 64 GB. See Defining a page set to be larger than 4 GB for instructions.

How to balance loads on page sets

Load balancing on page sets means moving the messages associated with one or more queues from one page set to another, less used, page set. Use this technique if it is not practical to expand the page set.

To identify which queues are using a page set, use the appropriate IBM MQ commands. For example, to find out which queues are mapped to page set 02, first, find out which storage classes map to page set 02, by using the command:

```
DISPLAY STGCLASS(*) PSID(02)
```

Then use the following command to find out which queues use which storage class:

```
DISPLAY QUEUE(*) TYPE(QLOCAL) STGCLASS
```

Moving a non-shared queue

To move queues and their messages from one page set to another, use the MQSC MOVE QLOCAL command (described in MOVE QLOCAL). When you have identified the queue or queues that you want to move to a new page set, follow this procedure for each of these queues:

1. Ensure that the queue you want to move is not in use by any applications (that is, IPPROCS and OPPROCS values from the DISPLAY QSTATUS command are zero) and that it has no uncommitted messages (the UNCOM value from the DISPLAY QSTATUS command is NO).

   Note: The only way to ensure that this state continues is to change your security settings temporarily. If you cannot do this, later stages in this procedure might fail if applications start to use the queue despite precautionary steps such as setting PUT(DISABLED). However, messages can never be lost by this procedure.
2. Prevent applications from putting messages on the queue being moved by altering the queue definition to disable **MQPUT** s. Change the queue definition to PUT(DISABLED).
3. Define a temporary queue with the same attributes as the queue that is being moved, using the command:

```
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED)
```

   Note: If this temporary queue already exists from a previous run, delete it before doing the define.
4. Move the messages to the temporary queue using the following command:

```
MOVE QLOCAL(QUEUE_TO_MOVE) TOQLOCAL(TEMP_QUEUE)
```

5. Delete the queue you are moving, using the command:

```
DELETE QLOCAL(QUEUE_TO_MOVE)
```

6. Define a new storage class that maps to the required page set, for example:

```
DEFINE STGCLASS(NEW) PSID(nn)
```

   Add the new storage class definition to the CSQINP2 data sets ready for the next queue manager restart.
7. Redefine the queue that you are moving, by changing the storage class attribute:

```
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) STGCLASS(NEW)
```

When the queue is redefined, it is based on the temporary queue created in step 3 on page 319.

8. Move the messages back to the new queue, using the command:

```
MOVE QLOCAL(TEMP) TOQLOCAL(QUEUE_TO_MOVE)
```

9. The queue created in step 3 on page 319 is no longer required. Use the following command to delete it:

```
DELETE QL(TEMP_QUEUE)
```

10. If the queue being moved was defined in the CSQINP2 data sets, change the STGCLASS attribute of the appropriate DEFINE QLOCAL command in the CSQINP2 data sets. Add the REPLACE keyword so that the existing queue definition is replaced.

Figure 44 shows an extract from a load balancing job.

```
//UTILITY EXEC PGM=CSQUTIL,PARM=('CSQ1')
//STEPLIB DD  DSN=thlqual.SCSQANLE,DISP=SHR
//     DD  DSN=thlqual.SCSQAUTH,DISP=SHR
//SYSPRINT DD  SYSOUT=*
//SYSIN  DD  *
COMMAND DDNAME(MOVEQ)
/*
//MOVEQ DD  *
ALTER QL(QUEUE_TO_MOVE) PUT(DISABLED)
DELETE QL(TEMP_QUEUE) PURGE
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED)
MOVE QLOCAL(QUEUE_TO_MOVE) TOQLOCAL(TEMP_QUEUE)
DELETE QL(QUEUE_TO_MOVE)
DEFINE STGCLASS(NEW) PSID(2)
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) STGCLASS(NEW)
MOVE QLOCAL(TEMP_QUEUE) TOQLOCAL(QUEUE_TO_MOVE)
DELETE QL(TEMP_QUEUE)
/*
```

Figure 44. Extract from a load balancing job for a page set

How to increase the size of a page set

You can initially allocate a page set larger than 4 GB, See Defining a page set to be larger than 4 GB

A page set can be defined to be automatically expanded as it becomes full by specifying EXPAND(SYSTEM) or EXPAND(USER). If your page set was defined with EXPAND(NONE), you can expand it in either of two ways:

- Alter its definition to allow automatic expansion. See Altering a page set to allow automatic expansion
- Create a new, larger page set and copy the messages from the old page set to the new one. See Moving messages to a new, larger page set

Defining a page set to be larger than 4 GB

IBM MQ can use a page set up to 64 GB in size, provided the data set is defined with 'extended addressability' to VSAM. Extended addressability is an attribute which is conferred by an SMS data class. In the example shown in the following sample JCL, the management class 'EXTENDED' is defined to SMS with 'Extended addressability'. If your existing page set is not currently defined as having extended addressability, use the following method to migrate to an extended addressability format data set.

1. Stop the queue manager.
2. Use Access Method Services to rename the existing page set.
3. Define a destination page set, the same size as the existing page set, but with DATACLASS(EXTENDED).
4. Use the COPYPAGE function of CSQUTIL to copy all the messages from the source page set to the destination page set. See Expanding a page set (COPYPAGE) for more details.
5. Restart the queue manager.
6. Alter the page set to use system expansion, to allow it to continue growing beyond its current allocation.

The following JCL shows example Access Method Services commands:

```
//S1    EXEC PGM=IDCAMS
//SYSPRINT DD  SYSOUT=*
//SYSIN   DD  *
ALTER 'VICY.CSQ1.PAGE01' -
NEWNAME('VICY.CSQ1.PAGE01.OLD')
ALTER 'VICY.CSQ1.PAGE01.DATA' -
NEWNAME('VICY.CSQ1.PAGE01.DATA.OLD')
DEFINE CLUSTER (NAME('VICY.CSQ1.PAGE01') -
MODEL('VICY.CSQ1.PAGE01.OLD') -
DATACLASS(EXTENDED))
/*
```

Altering a page set to allow automatic expansion

Use the ALTER PSID command with the EXPAND(USER) or EXPAND(SYSTEM) options. See ALTER PSID and Expanding a page set (COPYPAGE) for general information on expanding page sets.

Moving messages to a new, larger page set

This technique involves stopping and restarting the queue manager. This deletes any nonpersistent messages that are not on shared queues at restart time. If you have nonpersistent messages that you do not want to be deleted, use load balancing instead. For more details, see “How to balance loads on page sets” on page 318. In this description, the page set that you want to expand is referred to as the *source* page set; the new, larger page set is referred to as the *destination* page set.

Follow these steps:

1. Stop the queue manager.
2. Define the destination page set, ensuring that it is larger than the source page set, with a larger secondary extent value.
3. Use the FORMAT function of CSQUTIL to format the destination page set. See Formatting page sets (FORMAT) for more details.
4. Use the COPYPAGE function of CSQUTIL to copy all the messages from the source page set to the destination page set. See Expanding a page set (COPYPAGE) for more details.
5. Restart the queue manager using the destination page set by doing one of the following:
   - Change the queue manager started task procedure to reference the destination page set.

- Use Access Method Services to delete the source page set and then rename the destination page set, giving it the same name as that of the source page set.

Attention:

Before you delete any IBM MQ page set, be sure that you have made the required backup copies.

How to reduce a page set

Prevent all users, other than the IBM MQ administrator, from using the queue manager. For example; by changing the access security settings.

If you have a large page set that is mostly empty (as shown by the DISPLAY USAGE command), you might want to reduce its size. The procedure to do this involves using the COPY, FORMAT, and LOAD functions of CSQUTIL (see IBM MQ utility program). This procedure does not work for page set zero (0), as it is not practical to reduce the size of this page set; the only way to do so is by reinitializing your queue manager (see “Reinitializing a queue manager” on page 340). The prerequisite of this procedure is to try and remove all users from the system so that all UOWs are complete and the page sets are consistent.

1. Use the STOP QMGR command with the `QUIESCE` or `FORCE` attribute to stop the queue manager.
2. Run the SCOPY function of CSQUTIL with the `PSID` option, to copy all message data from the large page set and save them in a sequential data set.
3. Define a new smaller page set data set to replace the large page set.
4. Run the FORMAT TYPE(NEW) function of CSQUTIL against the page set that you created in step 3.
5. Restart the queue manager using the page set created in step 3.
6. Run the LOAD function of CSQUTIL to load back all the messages saved during step 2.
7. Allow all users access to the queue manager.
8. Delete the old large page set.

How to reintroduce a page set

In certain scenarios it is useful to be able to bring an old page set online again to the queue manager. Unless specific action is taken, when the old page set is brought online the queue manager will recognize that the page set recovery RBA stored in the page set itself and in the checkpoint records is old, and will therefore automatically start media recovery of the page set to bring it up to date.

Such media recovery can only be performed at queue manager restart, and is likely to take a considerable length of time, especially if archive logs held on tape must be read. However, normally in this circumstance, the page set has been offline for the intervening period and so the log contains no information pertinent to the page set recovery.

The following three choices are available:

Allow full media recovery to be performed.

1. Stop the queue manager.
2. Ensure definitions are available for the page set in both the started task procedure for the queue manager and in the CSQINP1 initialization data set.
3. Restart the queue manager.

Allow any messages on the page set to be destroyed.

This choice is useful where a page set has been offline for a long time (some months, for example) and it has now been decided to reuse it for a different purpose.

1. Format the page set using the FORMAT function of CSQUTIL with the TYPE(NEW) option.

2. Add definitions for the page set to both the started task procedure for the queue manager and the CSQINP1 initialization data set.
3. Restart the queue manager.

Using the TYPE(NEW) option for formatting clears the current contents of the page set and tells the queue manager to ignore any historical information in the checkpoint about the page set.

Bring the page set online avoiding the media recovery process.
Use this technique only if you are sure that the page set has been offline since a clean shutdown of the queue manager. This choice is most appropriate where the page set has been offline for a short period, typically due to operational issues such as a backup running while the queue manager is being started.

1. Format the page set using the FORMAT function of CSQUTIL with the TYPE(REPLACE) option.
2. Either add the page set back into the queue manager dynamically using the DEFINE PSID command with the DSN option or allow it to be added at a queue manager restart.

Using the TYPE(REPLACE) option for formatting checks that the page set was cleanly closed by the queue manager, and marks it so that media recovery will not be performed. No other changes are made to the contents of the page set.

How to back up and recover page sets

There are different mechanisms available for back up and recovery. Use this topic to understand these mechanisms.

This section describes the following topics:

- "Creating a point of recovery for non-shared resources"
- "Backing up page sets" on page 324
- "Recovering page sets" on page 325
- How to delete page sets

For information about how to create a point of recovery for shared resources, see "Recovering shared queues" on page 331.

Creating a point of recovery for non-shared resources

IBM MQ can recover objects and non-shared persistent messages to their current state if both:

1. Copies of page sets from an earlier point exist.
2. All the IBM MQ logs are available to perform recovery from that point.

These represent a point of recovery for non-shared resources.

Both objects and messages are held on page sets. Multiple objects and messages from different queues can exist on the same page set. For recovery purposes, objects and messages cannot be backed up in isolation, so a page set must be backed up as a whole to ensure the correct recovery of the data.

The IBM MQ recovery log contains a record of all persistent messages and changes made to objects. If IBM MQ fails (for example, due to an I/O error on a page set), you can recover the page set by restoring the backup copy and restarting the queue manager. IBM MQ applies the log changes to the page set from the point of the backup copy.

There are two ways of creating a point of recovery:

Full backup
Stop the queue manager, which forces all updates on to the page sets.

This allows you to restart from the point of recovery, using only the backed up page set data sets and the logs from that point on.

Fuzzy backup

Take *fuzzy* backup copies of the page sets without stopping the queue manager.

If you use this method, and your associated logs later become damaged or lost, you cannot to use the fuzzy page set backup copies to recover. This is because the fuzzy page set backup copies contain an inconsistent view of the state of the queue manager and are dependent on the logs being available. If the logs are not available, you need to return to the last set of backup page set copies taken while the subsystem was inactive (Method 1) and accept the loss of data from that time.

Method 1: Full backup

This method involves shutting the queue manager down. This forces all updates on to the page sets so that the page sets are in a consistent state.

1. Stop all the IBM MQ applications that are using the queue manager (allowing them to complete first). This can be done by changing the access security or queue settings, for example.
2. When all activity has completed, display and resolve any in-doubt units of recovery. (Use the commands DISPLAY CONN and RESOLVE INDOUBT, as described in DISPLAY CONN and RESOLVE INDOUBT.)

   This brings the page sets to a consistent state; if you do not do this, your page sets might not be consistent, and you are effectively doing a fuzzy backup.
3. Issue the ARCHIVE LOG command to ensure that the latest log data is written out to the log data sets.
4. Issue the STOP QMGR MODE(QUIESCE) command. Record the lowest RBA value in the CSQI024I or CSQI025I messages (see CSQI024I and CSQI025I for more information). You should keep the log data sets starting from the one indicated by the RBA value up to the current log data set.
5. Take backup copies of all the queue manager page sets (see “Backing up page sets”).

Method 2: Fuzzy backup

This method does not involve shutting the queue manager down. Therefore, updates might be in virtual storage buffers during the backup process. This means that the page sets are not in a consistent state, and can only be used for recovery with the logs.

1. Issue the DISPLAY USAGE TYPE(ALL) command, and record the RBA value in the CSQI024I or CSQI025I messages (see CSQI024I and CSQI025I for more information).
2. Take backup copies of the page sets (see “Backing up page sets”).
3. Issue the ARCHIVE LOG command, to ensure that the latest log data is written out to the log data sets. To restart from the point of recovery, you must keep the log data sets starting from the log data set indicated by the RBA value up to the current log data set.

Backing up page sets

To recover a page set, IBM MQ needs to know how far back in the log to go. IBM MQ maintains a log RBA number in page zero of each page set, called the *recovery log sequence number* (LSN). This number is the starting RBA in the log from which IBM MQ can recover the page set. When you back up a page set, this number is also copied.

If the copy is later used to recover the page set, IBM MQ must have access to all the log records from this RBA value to the current RBA. That means you must keep enough of the log records to enable IBM MQ to recover from the oldest backup copy of a page set you intend to keep.

Use ADRDSSU COPY function to copy the page sets.

For more information, see the COPY DATASET Command Syntax for Logical Data Set documentation .

For example:

```
//STEP2 EXEC PGM=ADRDSSU,REGION=6M
//SYSPRINT DD SYSOUT=H
//SYSIN DD *
 COPY -
 DATASET(INCLUDE(SCENDATA.MQPA.PAGESET.*)) -
 RENAMEU(SCENDATA.MQPA.PAGESET.**,SCENDATA.MQPA.BACKUP1.**) -
 SPHERE -
 REPUNC -
 FASTREPLICATION(PREF )-
 CANCELERROR -
 TOL(ENQF)
/*
//
```

If you copy the page set while the queue manager is running you must use a copy utility that copies page zero of the page set first. If you do not do this you could corrupt the data in your page set.

If the process of dynamically expanding a page set is interrupted, for example by power to the system being lost, you can still use ADRDSSU to take a backup of a page set.

If you perform an Access Method Services IDCAMS `LISTCAT ENT('page set data set name') ALLOC`, you will see that the `HI-ALLOC-RBA` is higher than the `HI-USED-RBA`.

The next time this page set fills up it is extended again, if possible, and the pages between the high used RBA and the highest allocated RBA are used, along with another new extent.

Backing up your object definitions

You should also back up copies of your object definitions. To do this, use the MAKEDEF feature of the CSQUTIL COMMAND function (described in Issuing commands to IBM MQ (COMMAND)).

Back up your object definitions whenever you take a backup copy of your queue manager, and keep the most current version.

Recovering page sets

If the queue manager has terminated due to a failure, the queue manager can normally be restarted with all recovery being performed during restart. However, such recovery is not possible if any of your page sets or log data sets are not available. The extent to which you can now recover depends on the availability of backup copies of page sets and log data sets.

To restart from a point of recovery you must have:

- A backup copy of the page set that is to be recovered.
- If you used the “fuzzy” backup process described in “Method 2: Fuzzy backup” on page 324, the log data set that included the recorded RBA value, the log data set that was made by the ARCHIVE LOG command, and all the log data sets between these.
- If you used full backup, but you do not have the log data sets following that made by the ARCHIVE LOG command, you do **not** need to run the FORMAT TYPE(REPLACE) function of the CSQUTIL utility against all your page sets.

To recover a page set to its current state, you must also have all the log data sets and records since the ARCHIVE LOG command.

There are two methods for recovering a page set. To use either method, the queue manager must be stopped.

Simple recovery

This is the simpler method, and is appropriate for most recovery situations.

1. Delete the page set you want to restore from backup.
2. Use the ADRDSSU COPY function to recover your page set from the backup copy..

   Alternatively, you can rename your backup copy to the original name, or change the CSQP00xx DD statement in your queue manager procedure to point to your backup page set. However, if you then lose or corrupt the page set, you will no longer have a backup copy to restore from.
3. Restart the queue manager.
4. When the queue manager has restarted successfully, you can restart your applications
5. Reinstate your normal backup procedures for the restored page.

Advanced recovery

This method provides performance advantages if you have a large page set to recover, or if there has been much activity on the page set since the last backup copy was taken. However, it requires more manual intervention than the simple method, which might increase the risk of error and the time taken to perform the recovery.

1. Delete and redefine the page set you want to restore from backup.
2. Use ADRDSSU to copy the backup copy of the page set into the new page set. Define your new page set with a secondary extent value so that it can be expanded dynamically.

   Alternatively, you can rename your backup copy to the original name, or change the CSQP00xx DD statement in your queue manager procedure to point to your backup page set. However, if you then lose or corrupt the page set, you will no longer have a backup copy to restore from.
3. Change the CSQINP1 definitions for your queue manager to make the buffer pool associated with the page set being recovered as large as possible. By making the buffer pool large, you might be able to keep all the changed pages resident in the buffer pool and reduce the amount of I/O to the page set.
4. Restart the queue manager.
5. When the queue manager has restarted successfully, stop it (using quiesce) and then restart it using the normal buffer pool definition for that page set. After this second restart completes successfully, you can restart your applications
6. Reinstate your normal backup procedures for the restored page.

What happens when the queue manager is restarted

When the queue manager is restarted, it applies all changes made to the page set that are registered in the log, beginning at the restart point for the page set. IBM MQ can recover multiple page sets in this way. The page set is dynamically expanded, if required, during media recovery.

During restart, IBM MQ determines the log RBA to start from by taking the lowest value from the following:

- Recovery LSN from the checkpoint log record for each page set.
- Recovery LSN from page zero in each page set.
- The RBA of the oldest incomplete unit of recovery in the system at the time the backup was taken.

All object definitions are stored on page set zero. Messages can be stored on any available page set.

Note: The queue manager cannot restart if page set zero is not available.

How to delete page sets

You delete a page set by using the DELETE PSID command; see DELETE PSID for details of this command.

You cannot delete a page set that is still referenced by any storage class. Use DISPLAY STGCLASS to find out which storage classes reference a page set.

The data set is deallocated from IBM MQ but is not deleted. It remains available for future use, or can be deleted using z/OS facilities.

Remove the page set from the started task procedure for your queue manager.

Remove the definition of the page set from your CSQINP1 initialization data set.

How to back up and restore queues using CSQUTIL

Use this topic as a reference for further information about back up and restore using CSQUTIL.

You can use the CSQUTIL utility functions for backing up and restoring queues. To back up a queue, use the COPY or SCOPY function to copy the messages from a queue onto a data set. To restore the queue, use the complementary function LOAD or SLOAD. For more information, see IBM MQ utility program.

Managing buffer pools

Use this topic if you want to change or delete your buffer pools.

This topic describes how to alter and delete buffer pools. It contains these sections:
- “How to change the number of buffers in a buffer pool”
- “How to delete a buffer pool” on page 328

Buffer pools are defined during queue manager initialization, using DEFINE BUFFPOOL commands issued from the initialization input data set CSQINP1. Their attributes can be altered in response to business requirements while the queue manager is running, using the processes detailed in this topic. The queue manager records the current buffer pool attributes in checkpoint log records. These are automatically restored on subsequent queue manager restart, unless the buffer pool definition in CSQINP1 includes the REPLACE attribute.

Use the DISPLAY USAGE command to display the current buffer attributes.

You can also define buffer pools dynamically using the DEFINE PSID command with the DSN option.

If you change buffer pools dynamically, you should also update their definitions in the initialization data set CSQINP1.

See Planning on z/OS for a description of page sets, storage classes, buffers, and buffer pools, and some of the performance considerations that apply.

Note: Buffer pools use significant storage. When you increase the size of a buffer pool or define a new buffer pool ensure that sufficient storage is available. For more information, see Address space storage.

How to change the number of buffers in a buffer pool

If a buffer pool is too small, the condition can result in message CSQP020E on the console, you can allocate more buffers to it using the ALTER BUFFPOOL command as follows:

1. Determine how much space is available for new buffers by looking at the CSQY220I messages in the log. The available space is reported in MB. As a buffer has a size of 4 KB, each MB of available space allows you to allocate 256 buffers. Do not allocate all the free space to buffers, as some is required for other tasks.

   If the buffer pool uses fixed 4 KB pages, that is, its PAGECLAS attribute is FIXED4KB, ensure that there is sufficient real storage available on the LPAR.
2. If the reported free space is inadequate, release some buffers from another buffer pool using the command

   ```
   ALTER BUFFPOOL(buf-pool-id) BUFFERS(integer)
   ```

   where *buf-pool-id* is the buffer pool from which you want to reclaim space and *integer* is the new number of buffers to be allocated to this buffer pool, which must be smaller than the original number of buffers allocated to it.
3. Add buffers to the buffer pool you want to expand using the command

   ```
   ALTER BUFFPOOL(buf-pool-id) BUFFERS(integer)
   ```

   where *buf-pool-id* is the buffer pool to be expanded and *integer* is the new number of buffers to be allocated to this buffer pool, which must be larger than the original number of buffers allocated to it.

How to delete a buffer pool

When a buffer pool is no longer used by any page sets, delete it to release the virtual storage allocated to it.

You delete a buffer pool using the DELETE BUFFPOOL command. The command fails if any page sets are using this buffer pool.

See "How to delete page sets" on page 327 for information about how to delete page sets.

Managing queue-sharing groups and shared queues

IBM MQ can use different types of shared resources, for example queue-sharing groups, shared queues, and the coupling facility. Use this topic to review the procedures needed to manage these shared resources.

This section contains information about the following topics:
- "Managing queue-sharing groups" on page 329
- "Managing shared queues" on page 331
- "Managing group objects" on page 336
- "Managing the coupling facility" on page 336

Managing queue-sharing groups:

You can add or remove a queue manager to a queue-sharing group, and manage the associated Db2 tables.

This topic has sections about the following tasks:
- “Adding a queue-sharing group to the Db2 tables”
- “Adding a queue manager to a queue-sharing group”
- “Removing a queue manager from a queue-sharing group”
- “Removing a queue-sharing group from the Db2 tables” on page 330
- “Validating the consistency of Db2 definitions” on page 330

Adding a queue-sharing group to the Db2 tables

To add a queue-sharing group to the Db2 tables, use the ADD QSG function of the queue-sharing group utility (CSQ5PQSG). This program is described in The queue-sharing group utility. A sample is provided in thlqual.SCSQPROC(CSQ45AQS).

Adding a queue manager to a queue-sharing group

A queue manager can be added to a queue-sharing group and this topic describes some of the limitations.

To add a queue manager to a queue-sharing group, use the ADD QMGR function of the queue-sharing group utility (CSQ5PQSG). This program is described in The queue-sharing group utility. A sample is provided in thlqual.SCSQPROC(CSQ45AQM).

The queue-sharing group must exist before you can add queue managers to it.

Queue-sharing groups have a name of up to four characters. The name must be unique in your network, and must be different from any queue manager names.

A queue manager can only be a member of one queue-sharing group.

Note: To add a queue manager to an existing queue-sharing group containing queue managers running earlier versions of IBM MQ, you must first apply the coexistence PTF for the highest version of IBM MQ in the group to every earlier version queue manager in the group.

Removing a queue manager from a queue-sharing group

You can only remove a queue manager from a queue-sharing group if the queue manager's logs are not needed by another process. The logs are needed if they contain:
- the latest backup of one of the coupling facility (CF) application structures used by the queue-sharing group
- data needed by a future restore process, that is, the queue manager has used a recoverable structure since the time described by the last backup exclusion interval value.

If either or both of these points apply, the queue manager cannot be removed. To determine which queue managers' logs are needed for a future restore process, use the MQSC DISPLAY CFSTATUS command with the TYPE(BACKUP) option (for details of this command, see DISPLAY CFSTATUS).

If the queue manager logs are not needed, take the following steps to remove the queue manager from the queue-sharing group:
1. Resolve any indoubt units of work involving this queue manager.

2. Shut the queue manager down cleanly using STOP QMGR MODE(QUIESCE).
3. Wait for an interval at least equivalent to the value of the EXCLINT parameter you will specify in the BACKUP CFSTRUCT command in the next step.
4. On another queue manager, run a CF structure backup for each recoverable CF structure by using the MQSC BACKUP CFSTRUCT command and specifying an EXCLINT value as required in the previous step.
5. Use the REMOVE QMGR function of the CSQ5PQSG utility to remove the queue manager from the queue-sharing group. This program is described in The queue-sharing group utility. A sample is provided in thlqual.SCSQPROC(CSQ45RQM).
6. Before restarting the queue manager, reset the QSGDATA system parameter to its default value. See Using CSQ6SYSP for information about how to tailor your system parameters.

Note, that when removing the last queue manager in a queue sharing group, you must use the FORCE option, rather than REMOVE. This removes the queue manager from the queue sharing group, while not performing the consistency checks of the queue manager logs being required for recovery. You should only perform this operation if you are deleting the queue sharing group.

Removing a queue-sharing group from the Db2 tables

To remove a queue-sharing group from the Db2 tables, use the REMOVE QSG function of the queue-sharing group utility (CSQ5PQSG). This program is described in The queue-sharing group utility. A sample is provided in thlqual.SCSQPROC(CSQ45RQS).

You can only remove a queue-sharing group from the common Db2 data-sharing group tables after you have removed all the queue managers from the queue-sharing group (as described in "Removing a queue manager from a queue-sharing group" on page 329).

When the queue-sharing group record is deleted from the queue-sharing group administration table, all objects and administrative information relating to that queue-sharing group are deleted from other IBM MQ Db2 tables. This includes shared queue and group object information.

Validating the consistency of Db2 definitions

Problems for shared queues within a queue-sharing group can occur if the Db2 object definitions have, for any reason, become inconsistent.

To validate the consistency of the Db2 object definitions for queue managers, CF structures, and shared queues, use the VERIFY QSG function of the queue-sharing group utility (CSQ5PQSG). This program is described in The queue-sharing group utility.

Managing shared queues:

Use this topic to understand how to recover, move, and migrate shared queues.

This section describes the following tasks:
- “Recovering shared queues”
- “Moving shared queues”
- “Migrating non-shared queues to shared queues” on page 334
- Suspending a Db2 connection

Recovering shared queues

IBM MQ can recover persistent messages on shared queues if all:
- Backups of the CF structures containing the messages have been performed.
- All the logs for all queue managers in the queue-sharing group are available, to perform recovery from the point the backups are taken.
- Db2 is available and the structure backup table is more recent that the most recent CF structure backup.

The messages on a shared queue are stored in a coupling facility (CF) structure. Persistent messages can be put onto shared queues, and like persistent messages on non-shared queues, they are copied to the queue manager log. The MQSC BACKUP CFSTRUCT and RECOVER CFSTRUCT commands are provided to allow the recovery of a CF structure in the unlikely event of a coupling facility failure. In such circumstances, any nonpersistent messages stored in the affected structure are lost, but persistent messages can be recovered. Any further application activity using the structure is prevented until the structure has been recovered.

To enable recovery, you must back up your coupling facility list structures frequently using the MQSC BACKUP CFSTRUCT command. The messages in the CF structure are written onto the active log data set of the queue manager making the backup. It writes a record of the backup to Db2: the name of the CF structure being backed up, the name of the queue manager doing the backup, the RBA range for this backup on that queue manager log, and the backup time. Back up CF list structures even if you are not actively using shared queues, for example, if you have set up a queue-sharing group intending to use it in the future.

You can recover a CF structure by issuing an MQSC RECOVER CFSTRUCT command to the queue manager that can perform the recovery; you can use any queue manager in the queue-sharing group. You can specify a single CF structure to be recovered, or you can recover several CF structures simultaneously.

As noted previously, it is important that you back up your CF list structures frequently, otherwise recovering a CF structure can take a long time. Moreover, the recovery process cannot be canceled.

The definition of a shared queue is kept in a Db2 database and can therefore be recovered if necessary using standard Db2 database procedures. See Shared queues and queue-sharing groups for more information.

Moving shared queues

This section describes how to perform load balancing by moving a shared queue from one coupling facility structure to another. It also describes how to move a non-shared queue to a shared queue, and how to move a shared queue to a non-shared queue.

When you move a queue, you need to define a temporary queue as part of the procedure. This is because every queue must have a unique name, so you cannot have two queues of the same name, even if the queues have different queue dispositions. IBM MQ tolerates having two queues with the same name (as in step 2), but you cannot use the queues.

- Moving a queue from one coupling facility structure to another
- Moving a non-shared queue to a shared queue
- Moving a shared queue to a non-shared queue

Moving a queue from one coupling facility structure to another

To move queues and their messages from one CF structure to another, use the MQSC MOVE QLOCAL command. When you have identified the queue or queues that you want to move to a new CF structure, use the following procedure to move each queue:

1. Ensure that the queue you want to move is not in use by any applications, that is, the queue attributes IPPROCS and OPPROCS are zero on all queue managers in the queue-sharing group.
2. Prevent applications from putting messages on the queue being moved by altering the queue definition to disable **MQPUT** s. Change the queue definition to PUT(DISABLED).
3. Define a temporary queue with the same attributes as the queue that is being moved using the following command:

```
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED) QSGDISP(QMGR)
```

   Note: If this temporary queue exists from a previous run, delete it before doing the define.
4. Move the messages to the temporary queue using the following command:

```
MOVE QLOCAL(QUEUE_TO_MOVE) TOQLOCAL(TEMP_QUEUE)
```

5. Delete the queue you are moving, using the command:

```
DELETE QLOCAL(QUEUE_TO_MOVE)
```

6. Redefine the queue that is being moved, changing the CFSTRUCT attribute, using the following command:

```
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) CFSTRUCT(NEW) QSGDISP(SHARED)
```

   When the queue is redefined, it is based on the temporary queue created in step 3.
7. Move the messages back to the new queue using the command:

```
MOVE QLOCAL(TEMP) TOQLOCAL(QUEUE_TO_MOVE)
```

8. The queue created in step 3 on page 332 is no longer required. Use the following command to delete it:

```
DELETE QL(TEMP_QUEUE)
```

9. If the queue being moved was defined in the CSQINP2 data sets, change the CFSTRUCT attribute of the appropriate DEFINE QLOCAL command in the CSQINP2 data sets. Add the REPLACE keyword so that the existing queue definition is replaced.

Figure 45 shows a sample job for moving a queue from one CF structure to another.

```
//UTILITY EXEC PGM=CSQUTIL,PARM=('CSQ1')
//STEPLIB DD  DSN=thlqual.SCSQANLE,DISP=SHR
//      DD  DSN=thlqual.SCSQAUTH,DISP=SHR
//SYSPRINT DD  SYSOUT=*
//SYSIN  DD  *
COMMAND DDNAME(MOVEQ)
/*
//MOVEQ DD  *
ALTER QL(QUEUE_TO_MOVE) PUT(DISABLED)
DELETE QL(TEMP_QUEUE) PURGE
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED) QSGDISP(QMGR)
MOVE QLOCAL(QUEUE_TO_MOVE) TOQLOCAL(TEMP_QUEUE)
DELETE QL(QUEUE_TO_MOVE)
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) CFSTRUCT(NEW) QSGDISP(SHARED)
MOVE QLOCAL(TEMP_QUEUE) TOQLOCAL(QUEUE_TO_MOVE)
DELETE QL(TEMP_QUEUE)
/*
```

Figure 45. Sample job for moving a queue from one CF structure to another

Moving a non-shared queue to a shared queue

The procedure for moving a non-shared queue to a shared queue is like the procedure for moving a queue from one CF structure to another (see “Moving a queue from one coupling facility structure to another” on page 332). Figure 46 on page 334 gives a sample job to do this.

Note: Remember that messages on shared queues are subject to certain restrictions on the maximum message size, message persistence, and queue index type, so you might not be able to move some non-shared queues to a shared queue.

```
//UTILITY EXEC PGM=CSQUTIL,PARM=('CSQ1')
//STEPLIB DD  DSN=thlqual.SCSQANLE,DISP=SHR
//     DD  DSN=thlqual.SCSQAUTH,DISP=SHR
//SYSPRINT DD  SYSOUT=*
//SYSIN  DD  *
COMMAND DDNAME(MOVEQ)
/*
//MOVEQ DD  *
ALTER QL(QUEUE_TO_MOVE) PUT(DISABLED)
DELETE QL(TEMP_QUEUE) PURGE
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED)
MOVE QLOCAL(QUEUE_TO_MOVE) TOQLOCAL(TEMP_QUEUE)
DELETE QL(QUEUE_TO_MOVE)
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) CFSTRUCT(NEW) QSGDISP(SHARED)
MOVE QLOCAL(TEMP_QUEUE) TOQLOCAL(QUEUE_TO_MOVE)
DELETE QL(TEMP_QUEUE)
/*
```

Figure 46. Sample job for moving a non-shared queue to a shared queue

Moving a shared queue to a non-shared queue

The procedure for moving a shared queue to a non-shared queue is like the procedure for moving a queue from one CF structure to another (see "Moving a queue from one coupling facility structure to another" on page 332).

Figure 47 gives a sample job to do this.

```
//UTILITY EXEC PGM=CSQUTIL,PARM=('CSQ1')
//STEPLIB DD  DSN=thlqual.SCSQANLE,DISP=SHR
//     DD  DSN=thlqual.SCSQAUTH,DISP=SHR
//SYSPRINT DD  SYSOUT=*
//SYSIN  DD  *
COMMAND DDNAME(MOVEQ)
/*
//MOVEQ DD  *
ALTER QL(QUEUE_TO_MOVE) PUT(DISABLED)
DELETE QL(TEMP_QUEUE) PURGE
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED) QSGDISP(QMGR)
MOVE QLOCAL(QUEUE_TO_MOVE) TOQLOCAL(TEMP_QUEUE)
DELETE QL(QUEUE_TO_MOVE)
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) STGCLASS(NEW) QSGDISP(QMGR)
MOVE QLOCAL(TEMP_QUEUE) TOQLOCAL(QUEUE_TO_MOVE)
DELETE QL(TEMP_QUEUE)
/*
```

Figure 47. Sample job for moving a shared queue to a non-shared queue

Migrating non-shared queues to shared queues

There are two stages to migrating non-shared queues to shared queues:
- Migrating the first (or only) queue manager in the queue-sharing group
- Migrating any other queue managers in the queue-sharing group

Migrating the first (or only) queue manager in the queue-sharing group

Figure 46 shows an example job for moving a non-shared queue to a shared queue. Do this for each queue that needs migrating.

Note:

1. Messages on shared queues are subject to certain restrictions on the maximum message size, message persistence, and queue index type, so you might not be able to move some non-shared queues to a shared queue.
2. You must use the correct index type for shared queues. If you migrate a transmission queue to be a shared queue, the index type must be MSGID.

If the queue is empty, or you do not need to keep the messages that are on it, migrating the queue is simpler. Figure 48 shows an example job to use in these circumstances.

```
//UTILITY EXEC PGM=CSQUTIL,PARM=('CSQ1')
//STEPLIB DD  DSN=thlqual.SCSQANLE,DISP=SHR
//     DD  DSN=thlqual.SCSQAUTH,DISP=SHR
//SYSPRINT DD  SYSOUT=*
//SYSIN  DD  *
COMMAND DDNAME(MOVEQ)
/*
//MOVEQ DD  *
DELETE QL(TEMP_QUEUE) PURGE
DEFINE QL(TEMP_QUEUE) LIKE(QUEUE_TO_MOVE) PUT(ENABLED) GET(ENABLED)
DELETE QL(QUEUE_TO_MOVE)
DEFINE QL(QUEUE_TO_MOVE) LIKE(TEMP_QUEUE) CFSTRUCT(NEW) QSGDISP(SHARED)
DELETE QL(TEMP_QUEUE)
/*
```

Figure 48. Sample job for moving a non-shared queue without messages to a shared queue

Migrating any other queue managers in the queue-sharing group

1. For each queue that does not have the same name as an existing shared queue, move the queue as described in Figure 46 on page 334 or Figure 48.
2. For queues that have the same name as an existing shared queue, move the messages to the shared queue using the commands shown in Figure 49.

```
MOVE QLOCAL(QUEUE_TO_MOVE) QSGDISP(QMGR) TOQLOCAL(QUEUE_TO_MOVE)
DELETE QLOCAL(QUEUE_TO_MOVE) QSGDISP(QMGR)
```

Figure 49. Moving messages from a non-shared queue to an existing shared queue

Suspending a connection to Db2

If you want to apply maintenance or service to the Db2 tables or package related to shared queues without stopping your queue manager, you must temporarily disconnect queue managers in the data sharing group (DSG) from Db2.

To do this:

1. Use the MQSC command SUSPEND QMGR FACILITY(Db2).
2. Do the binds.
3. Reconnect to Db2 using the MQSC command RESUME QMGR FACILITY(Db2)

Note that there are restrictions on the use of these commands.

Attention: While the Db2 connection is suspended, the following operations will not be available. Therefore, you need to do this work during a time when your enterprise is at its least busy.

- Access to Shared queue objects for administration (define, delete,alter)
- Starting shared channels
- Storing messages in Db2
- Backup or recover CFSTRUCT

Managing group objects:

Use this topic to understand how to work with group objects.

IBM MQ automatically copies the definition of a group object to page set zero of each queue manager that uses it. You can alter the copy of the definition temporarily, and IBM MQ allows you to refresh the page set copies from the repository copy. IBM MQ always tries to refresh the page set copies from the repository copy on start-up (for channel objects, this is done when the channel initiator restarts). This ensures that the page set copies reflect the version on the repository, including any changes that were made when the queue manager was inactive.

There are circumstances under which the refresh is not performed, for example:
- If a copy of the queue is open, a refresh that would change the usage of the queue fails.
- If a copy of a queue has messages on it, a refresh that would delete that queue fails.

In these circumstances, the refresh is not performed on that copy, but is performed on the copies on all other queue managers. Check for and correct any problems with copy objects after adding, changing, or deleting a group object, and at queue manager or channel initiator restart.

Managing the coupling facility:

Use this topic to understand how to add or remove coupling facility (CF) structures.

This section describes the following tasks:
- "Adding a coupling facility structure"
- "Removing a coupling facility structure"

Adding a coupling facility structure

There are no IBM MQ actions required when you add a coupling facility structure. The information about setting up the coupling facility in Task 10: Set up the coupling facility describes the rules for naming coupling facility structures, and how to define structures in the CFRM policy data set.

Removing a coupling facility structure

To remove a coupling facility structure, follow this procedure:
- Use the following command to get a list of all the queues using the coupling facility structure that you want to delete:

```
DISPLAY QUEUE(*) QSGDISP(SHARED) CFSTRUCT(structure-name)
```

- Delete all the queues that use the structure.
- Stop and restart each queue manager in the queue-sharing group in turn to disconnect IBM MQ and Db2 from the structure and delete information about it. (You do not need to stop all the queue managers at once; just one at a time.)
- Remove the structure definition from your CFRM policy data set and run the IXCMIAPU utility. (This is the reverse of customization task 10 (set up the coupling facility) described in Task 10: Set up the coupling facility.)

Recovery and restart

Use this topic to understand the recovery and restart mechanisms used by IBM MQ.

Restarting IBM MQ

After a queue manager terminates there are different restart procedures needed depending on how the queue manager terminated. Use this topic to understand the different restart procedures that you can use.

This topic contains information about how to restart your queue manager in the following circumstances:

- "Restarting after a normal shutdown"
- "Restarting after an abnormal termination"
- "Restarting if you have lost your page sets"
- "Restarting if you have lost your log data sets"
- Restarting if you have lost your CF structures

Restarting after a normal shutdown

If the queue manager was stopped with the STOP QMGR command, the system finishes its work in an orderly way and takes a termination checkpoint before stopping. When you restart the queue manager, it uses information from the system checkpoint and recovery log to determine the system status at shutdown.

To restart the queue manager, issue the START QMGR command as described in "Starting and stopping a queue manager" on page 268.

Restarting after an abnormal termination

IBM MQ automatically detects whether restart follows a normal shutdown or an abnormal termination.

Starting the queue manager after it has terminated abnormally is different from starting it after the STOP QMGR command has been issued. If the queue manager terminates abnormally, it terminates without being able to finish its work or take a termination checkpoint.

To restart the queue manager, issue the START QMGR command as described in "Starting and stopping a queue manager" on page 268. When you restart a queue manager after an abnormal termination, it refreshes its knowledge of its status at termination using information in the log, and notifies you of the status of various tasks.

Normally, the restart process resolves all inconsistent states. But, in some cases, you must take specific steps to resolve inconsistencies. This is described in "Recovering units of work manually" on page 354.

Restarting if you have lost your page sets

If you have lost your page sets, you need to restore them from your backup copies before you can restart the queue manager. This is described in "How to back up and recover page sets" on page 323.

The queue manager might take a long time to restart under these circumstances because of the length of time needed for media recovery.

Restarting if you have lost your log data sets

If, after stopping a queue manager (using the STOP QMGR command), both copies of the log are lost or damaged, you can restart the queue manager providing you have a consistent set of page sets (produced using Method 1: Full backup).

Follow this procedure:

1. Define new page sets to correspond to each existing page set in your queue manager. See Task 15: Define your page sets for information about page set definition.

   Ensure that each new page set is larger than the corresponding source page set.
2. Use the FORMAT function of CSQUTIL to format the destination page set. See Formatting page sets for more details.
3. Use the RESETPAGE function of CSQUTIL to copy the existing page sets or reset them in place, and reset the log RBA in each page. See Copying a page set and resetting the log for more information about this function.
4. Redefine your queue manager log data sets and BSDS using CSQJU003 (see The change log inventory utility).
5. Restart the queue manager using the new page sets. To do this, you do one of the following:
   - Change the queue manager started task procedure to reference the new page sets. See Task 6: Create procedures for the IBM MQ queue manager for more information.
   - Use Access Method Services to delete the old page sets and then rename the new page sets, giving them the same names as the old page sets.

Attention: Before you delete any IBM MQ page set, ensure that you have made the required backup copies.

If the queue manager is a member of a queue-sharing group, GROUP and SHARED object definitions are not normally affected by lost or damaged logs. However, if any shared-queue messages are involved in a unit of work that was covered by the lost or damaged logs, the effect on such uncommitted messages is unpredictable.

Note: If logs are damaged and the queue manager is a member of a queue-sharing group, the ability to recover shared persistent messages might be lost. Issue a BACKUP CFSTRUCT command immediately on another active queue manager in the queue-sharing group for all CF structures with the RECOVER(YES) attribute.

Restarting if you have lost your CF structures

You do not need to restart if you lose your CF structures, because the queue manager does not terminate.

Recovering a queue-sharing group at the alternative site:

If you need to recover a queue-sharing group, you must understand the steps needed to prepare the recovery, and the steps needed to recover the queue managers in the queue-sharing group.

Before you can recover the queue-sharing group, you need to prepare the environment:

1. If you have old information in your coupling faciltiy from practice startups when you installed the queue-sharing group, you need to clean this out first (if you do not have old information in the coupling faciltiy, you can omit this step:
   a. Enter the following z/OS command to display the CF structures for this queue-sharing group:

```
D XCF,STRUCTURE,STRNAME= qsgname*
```

b. For all structures that start with the queue-sharing group name, use the z/OS command SETXCF FORCE CONNECTION to force the connection off those structures:

```
SETXCF FORCE,CONNECTION,STRNAME= strname,CONNAME=ALL
```

c. Delete all the CF structures using the following command for each structure:

```
SETXCF FORCE,STRUCTURE,STRNAME= strname
```

2. Restore Db2 systems and data-sharing groups.
3. Recover the CSQ.ADMIN_B_STRBACKUP table so that it contains information about the most recent structure backups taken at the prime site.

   Note: It is important that the STRBACKUP table contains the most recent structure backup information. Older structure backup information might require data sets that you have discarded as a result of the information given by a recent DISPLAY USAGE TYPE(DATASET) command, which would mean that your recovered CF structure would not contain accurate information.
4. Run the ADD QMGR command of the CSQ5PQSG utility for every queue manager in the queue-sharing group. This will restore the XCF group entry for each queue manager.

   When you run the utility in this scenario, the following messages are normal:

```
CSQU566I Unable to get attributes for admin structure, CF not found
or not allocated
CSQU546E Unable to add QMGR <queue-manager-name> entry,
already exists in Db2 table CSQ.ADMIN_B_QMGR
CSQU148I CSQ5PQSG Utility completed, return code=4
```

To recover the queue managers in the queue-sharing group:

1. Define new page set data sets and load them with the data in the copies of the page sets from the primary site.
2. Define new active log data sets.
3. Define a new BSDS data set and use Access Method Services REPRO to copy the *most recent* archived BSDS into it.
4. Use the print log map utility CSQJU004 to print information from this most recent BSDS. At the time this BSDS was archived, the most recent archived log you have would have just been truncated as an active log, and does not appear as an archived log. Record the STARTRBA, STARTLRSN, ENDRBA, and ENDLRSN values of this log.
5. Use the change log inventory utility, CSQJU003, to register this latest archive log data set in the BSDS that you have just restored, using the values recorded in Step 4.
6. Use the DELETE option of CSQJU003 to remove all active log information from the BSDS.
7. Use the NEWLOG option of CSQJU003 to add active logs to the BSDS, do not specify STARTRBA or ENDRBA.
8. Calculate the `recoverylrsn` for the queue-sharing group. The `recoverylrsn` is the lowest of the ENDLRSNs across all queue managers in the queue-sharing group (as recorded in Step 4), minus 1. For example, if there are two queue managers in the queue-sharing group, and the ENDLRSN for one of them is B713 3C72 22C5, and for the other is B713 3D45 2123, the `recoverylrsn` is B713 3C72 22C4.
9. Use CSQJU003 to add a restart control record to the BSDS. Specify:

```
CRESTART CREATE,ENDLRSN= recoverylrsn
```

where *recoverylrsn* is the value you recorded in Step 8 on page 339.

The BSDS now describes all active logs as being empty, all the archived logs you have available, and no checkpoints beyond the end of your logs.

You must add the CRESTART record to the BSDS for each queue manager within the queue-sharing group.

10. Restart each queue manager in the queue-sharing group with the usual START QMGR command. During initialization, an operator reply message such as the following is issued:

```
CSQJ245D +CSQ1 RESTART CONTROL INDICATES TRUNCATION AT RBA highrba.
REPLY Y TO CONTINUE, N TO CANCEL
```

Reply `Y` to start the queue manager. The queue manager starts, and recovers data up to ENDRBA specified in the CRESTART statement.

At IBM MQ Version 7.0.1 and later, the first queue manager started can rebuild the admin structure partitions for other members of the queue sharing group as well as its own, and it is no longer necessary to restart each queue manager in the queue sharing group at this stage.

11. When the admin structure data for all queue managers has been rebuilt, issue a RECOVER CFSTRUCT command for each CF application structure.

If you issue the RECOVER CFSTRUCT command for all structures on a single queue manager, the log merge process is only performed once, so is quicker than issuing the command on a different queue manager for each CF structure, where each queue manager has to perform the log merge step.

When conditional restart processing is used in a queue sharing group, IBM WebSphere MQ Version 7.0.1 and later queue managers, performing peer admin rebuild, check that peers BSDS contain the same CRESTART LRSN as their own. This is to ensure the integrity of the rebuilt admin structure. It is therefore important to restart other peers in the QSG, so they can process their own CRESTART information, before the next unconditional restart of any member of the group.

Reinitializing a queue manager:

If the queue manager has terminated abnormally you might not be able to restart it. This could be because your page sets or logs have been lost, truncated, or corrupted. If this has happened, you might have to reinitialize the queue manager (perform a cold start).

Attention

Only perform a cold start if you cannot restart the queue manager any other way. Performing a cold start enables you to recover your queue manager and your object definitions; you will **not** be able to recover your message data. Check that none of the other restart scenarios described in this topic work for you before you do this.

When you have restarted, all your IBM MQ objects are defined and available for use, but there is no message data.

Note: Do not reinitialize a queue manager while it is part of a cluster. You must first remove the queue manager from the cluster (using RESET CLUSTER commands on the other queue managers in the cluster), then reinitialize it, and finally reintroduce it to the cluster as a new queue manager.

This is because during reinitialization, the queue manager identifier (QMID) is changed, so any cluster object with the old queue manager identifier must be removed from the cluster.

For further information see the following sections:
- Reinitializing a queue manager that is not in a queue-sharing group
- Reinitializing queue managers in a queue-sharing group

Reinitializing a queue manager that is not in a queue-sharing group

To reinitialize a queue manager, follow this procedure:
1. Prepare the object definition statements that to be used when you restart the queue manager. To do this, either:
   - If page set zero is available, use the CSQUTIL SDEFS function (see Producing a list of IBM MQ define commands). You must get definitions for all object types (authentication information objects, CF structures, channels, namelists, processes, queues, and storage classes).
   - If page set zero is not available, use the definitions from the last time you backed up your object definitions.
2. Redefine your queue manager data sets (do not do this until you have completed step 1).

   See creating the bootstrap and log data sets and defining your page sets for more information.
3. Restart the queue manager using the newly defined and initialized log data sets, BSDS, and page sets. Use the object definition input statements that you created in step 1 as input in the CSQINP2 initialization input data set.

Reinitializing queue managers in a queue-sharing group

In a queue-sharing group, reinitializing a queue manager is more complex. It might be necessary to reinitialize one or more queue managers because of page set or log problems, but there might also be problems with Db2 or the coupling facility to deal with. Because of this, there are a number of alternatives:

Cold start
Reinitializing the entire queue-sharing group involves forcing all the coupling facilities structures, clearing all object definitions for the queue-sharing group from Db2, deleting or redefining the logs and BSDS, and formatting page sets for all the queue managers in the queue-sharing group.

Shared definitions retained
Delete or redefine the logs and BSDS, format page sets for all queue managers in the queue-sharing group, and force all the coupling facilities structures. On restart, all messages will have been deleted. The queue managers re-create COPY objects that correspond to GROUP objects that still exist in the Db2 database. Any shared queues still exist and can be used.

Single queue manager reinitialized
Delete or redefine the logs and BSDS, and format page sets for the single queue manager (this deletes all its private objects and messages). On restart, the queue manager re-creates COPY objects that correspond to GROUP objects that still exist in the Db2 database. Any shared queues still exist, as do the messages on them, and can be used.

Point in time recovery of a queue-sharing group
This is the alternative site disaster recovery scenario.

Shared objects are recovered to the point in time achieved by Db2 recovery (described in A Db2 system fails). Each queue manager can be recovered to a point in time achievable from the backup copies available at the alternative site.

Persistent messages can be used in queue-sharing groups, and can be recovered using the MQSC RECOVER CFSTRUCT command. Note that this command recovers to the time of failure.

However, there is no recovery of nonpersistent shared queue messages; they are lost unless you have made backup copies independently using the COPY function of the CSQUTIL utility program.

It is not necessary to try to restore each queue manager to the same point in time because there are no interdependencies between the local objects on different queue managers (which are what is actually being recovered), and the queue manager resynchronization with Db2 on restart creates or deletes COPY objects as necessary on a queue manager by queue manager basis.

Alternative site recovery

z/OS

You can recover a single queue manager or a queue-sharing group, or consider disk mirroring.

See the following sections for more details:
- Recovering a single queue manager at an alternative site
- Recovering a queue-sharing group.
  - CF structure media recovery
  - Backing up the queue-sharing group at the prime site
  - Recovering a queue-sharing group at the alternative site
- Using disk mirroring

Recovering a single queue manager at an alternative site

If a total loss of an IBM MQ computing center occurs, you can recover on another queue manager or queue-sharing group at a recovery site. (See "Recovering a queue-sharing group at the alternative site" on page 345 for the alternative site recovery procedure for a queue-sharing group.)

To recover on another queue manager at a recovery site, you must regularly back up the page sets and the logs. As with all data recovery operations, the objectives of disaster recovery are to lose as little data, workload processing (updates), and time, as possible.

At the recovery site:
- The recovery queue managers **must** have the same names as the lost queue managers.
- The system parameter module (for example, CSQZPARM) used on each recovery queue manager must contain the same parameters as the corresponding lost queue manager.

When you have done this, reestablish all your queue managers as described in the following procedure. This can be used to perform disaster recovery at the recovery site for a single queue manager. It assumes that all that is available are:
- Copies of the archive logs and BSDSs created by normal running at the primary site (the active logs will have been lost along with the queue manager at the primary site).
- Copies of the page sets from the queue manager at the primary site that are the same age or older than the most recent archive log copies available.

You can use dual logging for the active and archive logs, in which case you need to apply the BSDS updates to both copies:
1. Define new page set data sets and load them with the data in the copies of the page sets from the primary site.
2. Define new active log data sets.
3. Define a new BSDS data set and use Access Method Services REPRO to copy the *most recent* archived BSDS into it.

4. Use the print log map utility CSQJU004 to print information from this most recent BSDS. At the time this BSDS was archived, the most recent archived log you have would have just been truncated as an active log, and does not appear as an archived log. Record the STARTRBA and ENDRBA of this log.
5. Use the change log inventory utility, CSQJU003, to register this latest archive log data set in the BSDS that you have just restored, using the STARTRBA and ENDRBA recorded in Step 4.
6. Use the DELETE option of CSQJU003 to remove all active log information from the BSDS.
7. Use the NEWLOG option of CSQJU003 to add active logs to the BSDS, do not specify STARTRBA or ENDRBA.
8. Use CSQJU003 to add a restart control record to the BSDS. Specify `CRESTART CREATE,ENDRBA=highrba`, where `highrba` is the high RBA of the most recent archive log available (found in Step 4), plus 1.

   The BSDS now describes all active logs as being empty, all the archived logs you have available, and no checkpoints beyond the end of your logs.
9. Restart the queue manager with the START QMGR command. During initialization, an operator reply message such as the following is issued:

```
CSQJ245D +CSQ1 RESTART CONTROL INDICATES TRUNCATION AT RBA highrba.
REPLY Y TO CONTINUE, N TO CANCEL
```

   Type `Y` to start the queue manager. The queue manager starts, and recovers data up to ENDRBA specified in the CRESTART statement.

See Using the IBM MQ utilities for information about using CSQJU003 and CSQJU004.

Figure 50 shows sample input statements for CSQJU003 for steps 6, 7, and 8:

```
* Step 6
DELETE DSNAME=MQM2.LOGCOPY1.DS01
DELETE DSNAME=MQM2.LOGCOPY1.DS02
DELETE DSNAME=MQM2.LOGCOPY1.DS03
DELETE DSNAME=MQM2.LOGCOPY1.DS04
DELETE DSNAME=MQM2.LOGCOPY2.DS01
DELETE DSNAME=MQM2.LOGCOPY2.DS02
DELETE DSNAME=MQM2.LOGCOPY2.DS03
DELETE DSNAME=MQM2.LOGCOPY2.DS04

* Step 7
NEWLOG DSNAME=MQM2.LOGCOPY1.DS01,COPY1
NEWLOG DSNAME=MQM2.LOGCOPY1.DS02,COPY1
NEWLOG DSNAME=MQM2.LOGCOPY1.DS03,COPY1
NEWLOG DSNAME=MQM2.LOGCOPY1.DS04,COPY1
NEWLOG DSNAME=MQM2.LOGCOPY2.DS01,COPY2
NEWLOG DSNAME=MQM2.LOGCOPY2.DS02,COPY2
NEWLOG DSNAME=MQM2.LOGCOPY2.DS03,COPY2
NEWLOG DSNAME=MQM2.LOGCOPY2.DS04,COPY2

* Step 8
CRESTART CREATE,ENDRBA=063000
```

Figure 50. Sample input statements for CSQJU003

The things you need to consider for restarting the channel initiator at the recovery site are like those faced when using ARM to restart the channel initiator on a different z/OS image. See"Using ARM in an IBM MQ network" on page 352for more information. Your recovery strategy should also cover recovery of the IBM MQ product libraries and the application programming environments that use IBM MQ (CICS , for example).

Other functions of the change log inventory utility (CSQJU003) can also be used in disaster recovery scenarios. The HIGHRBA function allows the update of the highest RBA written and highest RBA offloaded values within the bootstrap data set. The CHECKPT function allows the addition of new checkpoint queue records or the deletion of existing checkpoint queue records in the BSDS.

Attention: These functions might affect the integrity of your IBM MQ data. Only use them in disaster recovery scenarios under the guidance of IBM service personnel.

Fast copy techniques

If copies of all the page sets and logs are made while the queue manager is frozen, the copies will be a consistent set that can be used to restart the queue manager at an alternative site. They typically enable a much faster restart of the queue manager, as there is little media recovery to be performed.

Use the SUSPEND QMGR LOG command to freeze the queue manager. This command flushes buffer pools to the page sets, takes a checkpoint, and stops any further log write activity. Once log write activity has been suspended, the queue manager is effectively frozen until you issue a RESUME QMGR LOG command. While the queue manager is frozen, the page sets and logs can be copied.

By using copying tools such as FLASHCOPY or SNAPSHOT to rapidly copy the page sets and logs, the time during which the queue manager is frozen can be reduced to a minimum.

Within a queue-sharing group, however, the SUSPEND QMGR LOG command might not be such a good solution. To be effective, the copies of the logs must all contain the same point in time for recovery, which means that the SUSPEND QMGR LOG command must be issued on all queue managers within the queue-sharing group simultaneously, and therefore the entire queue-sharing group will be frozen for some time.

Recovering a queue-sharing group

In the event of a prime site disaster, you can restart a queue-sharing group at a remote site using backup data sets from the prime site. To recover a queue-sharing group you need to coordinate the recovery across all the queue managers in the queue-sharing group, and coordinate with other resources, primarily Db2. This section describes these tasks in detail.

- CF structure media recovery
- Backing up the queue-sharing group at the prime site
- Recovering a queue-sharing group at the alternative site

CF structure media recovery

Media recovery of a CF structure used to hold persistent messages on a shared queue, relies on having a backup of the media that can be forward recovered by the application of logged updates. Take backups of your CF structures periodically using the MQSC BACKUP CFSTRUCT command. All updates to shared queues (**MQGET** s and **MQPUT** s) are written on the log of the queue manager where the update is performed. To perform media recovery of a CF structure you must apply logged updates to that backup from the logs of **all** the queue managers that have used that CF structure. When you use the MQSC RECOVER CFSTRUCT command, IBM MQ automatically merges the logs from relevant queue managers, and applies the updates to the most recent backup.

The CF structure backup is written to the log of the queue manager that processed the BACKUP CFSTRUCT command, so there are no additional data sets to be collected and transported to the alternative site.

Backing up the queue-sharing group at the prime site

At the prime site you need to establish a consistent set of backups on a regular basis, which can be used in the event of a disaster to rebuild the queue-sharing group at an alternative site. For a single queue manager, recovery can be to an arbitrary point in time, typically the end of the logs available at the remote site. However, where persistent messages have been stored on a shared queue, the logs of all the queue managers in the queue-sharing group must be merged to recover shared queues, as any queue manager in the queue-sharing group might have performed updates (**MQPUT** s or **MQGET** s) on the queue.

For recovery of a queue-sharing group, you need to establish a point in time that is within the log range of the log data of all queue managers. However, as you can only **forward** recover media from the log, this point in time must be after the BACKUP CFSTRUCT command has been issued and after any page set backups have been performed. (Typically, the point in time for recovery might correspond to the end of a business day or week.)

The following diagram shows time lines for two queue managers in a queue-sharing group. For each queue manager, fuzzy backups of page sets are taken (see Method 2: Fuzzy backup). On queue manager A, a BACKUP CFSTRUCT command is issued. Subsequently, an ARCHIVE LOG command is issued on each queue manager to truncate the active log, and copy it to media offline from the queue manager, which can be transported to the alternative site. 'End of log' identifies the time at which the ARCHIVE LOG command was issued, and therefore marks the extent of log data typically available at the alternative site. The point in time for recovery must lie between the end of any page set or CF structure backups, and the earliest end of log available at the alternative site.

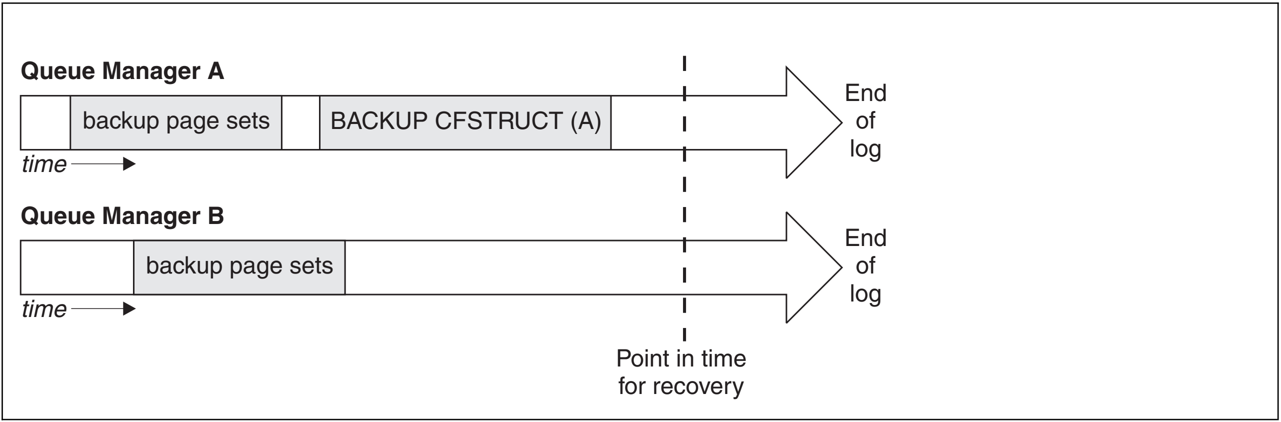

Figure 51. Point in time for recovery for 2 queue managers in a queue-sharing group

IBM MQ records information associated with the CF structure backups in a table in Db2. Depending on your requirements, you might want to coordinate the point in time for recovery of IBM MQ with that for Db2, or it might be sufficient to take a copy of the IBM MQ CSQ.ADMIN_B_STRBACKUP table after the BACKUP CFSTRUCT commands have finished.

To prepare for a recovery:

1. Create page set backups for each queue manager in the queue-sharing group.
2. Issue a BACKUP CFSTRUCT command for each CF structure with the RECOVER(YES) attribute. You can issue these commands from a single queue manager, or from different queue managers within the queue-sharing group to balance the workload.
3. Once all the backups have completed, issue an ARCHIVE LOG command to switch the active log and create copies of the logs and BSDSs of each queue manager in the queue-sharing group.
4. Transport the page set backups, the archived logs, the archived BSDS of all the queue managers in the queue-sharing group, and your chosen Db2 backup information, off-site.

Recovering a queue-sharing group at the alternative site

Before you can recover the queue-sharing group, you need to prepare the environment:

1. If you have old information in your coupling facility from practice startups when you installed the queue-sharing group, you need to clean this out first (if you do not have old information in the coupling facility, you can omit this step:
   a. Enter the following z/OS command to display the CF structures for this queue-sharing group:

```
D XCF,STRUCTURE,STRNAME= qsgname
```

   b. For all structures that start with the queue-sharing group name, use the z/OS command SETXCF FORCE CONNECTION to force the connection off those structures:

```
SETXCF FORCE,CONNECTION,STRNAME= strname,CONNAME=ALL
```

   c. Delete all the CF structures using the following command for each structure:

```
SETXCF FORCE,STRUCTURE,STRNAME= strname
```

2. Restore Db2 systems and data-sharing groups.
3. Recover the CSQ.ADMIN_B_STRBACKUP table so that it contains information about the most recent structure backups taken at the prime site.

   Note: It is important that the STRBACKUP table contains the most recent structure backup information. Older structure backup information might require data sets that you have discarded as a result of the information given by a recent DISPLAY USAGE TYPE(DATASET) command, which would mean that your recovered CF structure would not contain accurate information.
4. Run the ADD QMGR command of the CSQ5PQSG utility for every queue manager in the queue-sharing group. This will restore the XCF group entry for each queue manager.

To recover the queue managers in the queue-sharing group:

1. Define new page set data sets and load them with the data in the copies of the page sets from the primary site.
2. Define new active log data sets.
3. Define a new BSDS data set and use Access Method Services REPRO to copy the *most recent* archived BSDS into it.
4. Use the print log map utility CSQJU004 to print information from this most recent BSDS. At the time this BSDS was archived, the most recent archived log you have would have just been truncated as an active log, and does not appear as an archived log. Record the STARTRBA, STARTLRSN, ENDRBA, and ENDLRSN values of this log.
5. Use the change log inventory utility, CSQJU003, to register this latest archive log data set in the BSDS that you have just restored, using the values recorded in Step 4.
6. Use the DELETE option of CSQJU003 to remove all active log information from the BSDS.
7. Use the NEWLOG option of CSQJU003 to add active logs to the BSDS, do not specify STARTRBA or ENDRBA.
8. Calculate the `recoverylrsn` for the queue-sharing group. The `recoverylrsn` is the lowest of the ENDLRSNs across all queue managers in the queue-sharing group (as recorded in Step 4), minus 1. For example, if there are two queue managers in the queue-sharing group, and the ENDLRSN for one of them is B713 3C72 22C5, and for the other is B713 3D45 2123, the `recoverylrsn` is B713 3C72 22C4.

9. Use CSQJU003 to add a restart control record to the BSDS. Specify:

```
CRESTART CREATE,ENDLRSN= recoverylrsn
```

   where *recoverylrsn* is the value you recorded in Step 8 on page 346.

   The BSDS now describes all active logs as being empty, all the archived logs you have available, and no checkpoints beyond the end of your logs.

   You must add the CRESTART record to the BSDS for each queue manager within the queue-sharing group.

10. Restart each queue manager in the queue-sharing group with the START QMGR command. During initialization, an operator reply message such as the following is issued:

```
CSQJ245D +CSQ1 RESTART CONTROL INDICATES TRUNCATION AT RBA highrba.
REPLY Y TO CONTINUE, N TO CANCEL
```

   Reply Y to start the queue manager. The queue manager starts, and recovers data up to ENDRBA specified in the CRESTART statement.

   At IBM
   WebSphere MQ Version 7.0.1 and later, the first queue manager started can rebuild the admin structu

11. When the admin structure data for all queue managers has been rebuilt, issue a RECOVER CFSTRUCT command for each CF application structure.

   If you issue the RECOVER CFSTRUCT command for all structures on a single queue manager, the log merge process is only performed once, so is quicker than issuing the command on a different queue manager for each CF structure, where each queue manager has to perform the log merge step.

When conditional restart processing is used in a queue sharing group, IBM WebSphere MQ Version 7.0.1 and later queue managers, performing peer admin rebuild, check that peers BSDS contain the same CRESTART LRSN as their own. This is to ensure the integrity of the rebuilt admin structure. It is therefore important to restart other peers in the QSG, so they can process their own CRESTART information, before the next unconditional restart of any member of the group.

Using disk mirroring

Many installations now use disk mirroring technologies such as IBM Metro Mirror (formerly PPRC) to make synchronous copies of data sets at an alternative site. In such situations, many of the steps detailed become unnecessary as the IBM MQ page sets and logs at the alternative site are effectively identical to those at the prime site. Where such technologies are used, the steps to restart a queue sharing group at an alternative site may be summarized as:

- Clear IBM MQ CF structures at the alternative site. (These often contain residual information from any previous disaster recovery exercise).
- Restore Db2 systems and all tables in the database used by the IBM MQ queue sharing group.
- Restart queue managers. Before IBM WebSphere MQ Version 7.0.1, it is necessary to restart each queue manager defined in the queue sharing group as each queue manage recovers its own partition of the admin structure during queue manager restart. After each queue manager has been restarted, those not on their 'home' LPAR can be shut down again. For IBM WebSphere MQ Version 7.0.1 and later, the first queue manager started rebuilds the admin structure partitions for other members of the queue sharing group as well as its own, and it is no longer necessary to restart each queue manager in the queue sharing group.

- After the admin structure has been rebuilt, recover the application structures.

Reinitializing a queue manager

If the queue manager has terminated abnormally you might not be able to restart it. This could be because your page sets or logs have been lost, truncated, or corrupted. If this has happened, you might have to reinitialize the queue manager (perform a cold start).

Attention

Only perform a cold start if you cannot restart the queue manager any other way. Performing a cold start enables you to recover your queue manager and your object definitions; you will **not** be able to recover your message data. Check that none of the other restart scenarios described in this topic work for you before you do this.

When you have restarted, all your IBM MQ objects are defined and available for use, but there is no message data.

Note: Do not reinitialize a queue manager while it is part of a cluster. You must first remove the queue manager from the cluster (using RESET CLUSTER commands on the other queue managers in the cluster), then reinitialize it, and finally reintroduce it to the cluster as a new queue manager.

This is because during reinitialization, the queue manager identifier (QMID) is changed, so any cluster object with the old queue manager identifier must be removed from the cluster.

For further information see the following sections:
- Reinitializing a queue manager that is not in a queue-sharing group
- Reinitializing queue managers in a queue-sharing group

Reinitializing a queue manager that is not in a queue-sharing group

To reinitialize a queue manager, follow this procedure:
1. Prepare the object definition statements that to be used when you restart the queue manager. To do this, either:
   - If page set zero is available, use the CSQUTIL SDEFS function (see Producing a list of IBM MQ define commands). You must get definitions for all object types (authentication information objects, CF structures, channels, namelists, processes, queues, and storage classes).
   - If page set zero is not available, use the definitions from the last time you backed up your object definitions.
2. Redefine your queue manager data sets (do not do this until you have completed step 1 on page 341).

   See creating the bootstrap and log data sets and defining your page sets for more information.
3. Restart the queue manager using the newly defined and initialized log data sets, BSDS, and page sets. Use the object definition input statements that you created in step 1 on page 341 as input in the CSQINP2 initialization input data set.

Reinitializing queue managers in a queue-sharing group

In a queue-sharing group, reinitializing a queue manager is more complex. It might be necessary to reinitialize one or more queue managers because of page set or log problems, but there might also be problems with Db2 or the coupling facility to deal with. Because of this, there are a number of alternatives:

Cold start
Reinitializing the entire queue-sharing group involves forcing all the coupling facilities structures,

clearing all object definitions for the queue-sharing group from Db2, deleting or redefining the logs and BSDS, and formatting page sets for all the queue managers in the queue-sharing group.

Shared definitions retained
Delete or redefine the logs and BSDS, format page sets for all queue managers in the queue-sharing group, and force all the coupling facilities structures. On restart, all messages will have been deleted. The queue managers re-create COPY objects that correspond to GROUP objects that still exist in the Db2 database. Any shared queues still exist and can be used.

Single queue manager reinitialized
Delete or redefine the logs and BSDS, and format page sets for the single queue manager (this deletes all its private objects and messages). On restart, the queue manager re-creates COPY objects that correspond to GROUP objects that still exist in the Db2 database. Any shared queues still exist, as do the messages on them, and can be used.

Point in time recovery of a queue-sharing group
This is the alternative site disaster recovery scenario.

Shared objects are recovered to the point in time achieved by Db2 recovery (described in A Db2 system fails). Each queue manager can be recovered to a point in time achievable from the backup copies available at the alternative site.

Persistent messages can be used in queue-sharing groups, and can be recovered using the MQSC RECOVER CFSTRUCT command. Note that this command recovers to the time of failure. However, there is no recovery of nonpersistent shared queue messages; they are lost unless you have made backup copies independently using the COPY function of the CSQUTIL utility program.

It is not necessary to try to restore each queue manager to the same point in time because there are no interdependencies between the local objects on different queue managers (which are what is actually being recovered), and the queue manager resynchronization with Db2 on restart creates or deletes COPY objects as necessary on a queue manager by queue manager basis.

Using the z/OS Automatic Restart Manager (ARM)

Use this topic to understand how you can use ARM to automatically restart your queue managers.

This section contains information about the following topics:
- "What is the ARM?"
- "ARM policies" on page 350
- "Using ARM in an IBM MQ network" on page 352

What is the ARM?

The z/OS Automatic Restart Manager (ARM) is a z/OS recovery function that can improve the availability of your queue managers. When a job or task fails, or the system on which it is running fails, ARM can restart the job or task without operator intervention.

If a queue manager or a channel initiator has failed, ARM restarts it on the same z/OS image. If z/OS, and hence a whole group of related subsystems and applications have failed, ARM can restart all the failed systems automatically, in a predefined order, on another z/OS image within the sysplex. This is called a *cross-system restart*.

Restart the channel initiator by ARM only in exceptional circumstances. If the queue manager is restarted by ARM, restart the channel initiator from the CSQINP2 initialization data set (see "Using ARM in an IBM MQ network" on page 352).

You can use ARM to restart a queue manager on a different z/OS image within the sysplex in the event of z/OS failure. The network implications of IBM MQ ARM restart on a different z/OS image are described in "Using ARM in an IBM MQ network" on page 352.

To enable automatic restart:
- Set up an ARM couple data set.
- Define the automatic restart actions that you want z/OS to perform in an *ARM policy*.
- Start the ARM policy.

Also, IBM MQ must register with ARM at startup (this happens automatically).

Note: If you want to restart queue managers in different z/OS images automatically, you must define every queue manager as a subsystem in each z/OS image on which that queue manager might be restarted, with a sysplex wide unique four character subsystem name.

ARM couple data sets

Ensure that you define the couple data sets required for ARM, and that they are online and active before you start any queue manager for which you want ARM support. IBM MQ automatic ARM registration fails if the couple data sets are not available at queue manager startup. In this situation, IBM MQ assumes that the absence of the couple data set means that you do not want ARM support, and initialization continues.

See the *z/OS MVS Setting up a Sysplex* manual for information about ARM couple data sets.

ARM policies:

The Automatic Restart Manager policies are user-defined rules that control ARM functions that can control any restarts of a queue manager.

ARM functions are controlled by a user-defined *ARM policy*. Each z/OS image running a queue manager instance that is to be restarted by ARM must be connected to an ARM couple data set with an active ARM policy.

IBM provides a default ARM policy. You can define new policies, or override the policy defaults by using the *administrative data utility* (IXCMIAPU) provided with z/OS. The *z/OS MVS Setting up a Sysplex* manual describes this utility, and includes full details of how to define an ARM policy.

Figure 52 shows an example of an ARM policy. This sample policy restarts any queue manager within a sysplex, if either the queue manager failed, or a whole system failed.

```
//IXCMIAPU EXEC PGM=IXCMIAPU,REGION=2M
//SYSPRINT DD SYSOUT=*
//SYSIN  DD *
DATA TYPE(ARM)
DEFINE POLICY NAME(ARMPOL1) REPLACE(YES)
RESTART_GROUP(DEFAULT)
ELEMENT(*)
RESTART_ATTEMPTS(0)  /* Jobs not to be restarted by ARM  */
RESTART_GROUP(GROUP1)
ELEMENT(SYSMQMGRMQ*)  /* These jobs to be restarted by ARM */
/*
```

Figure 52. Sample ARM policy

For more information see:
- Defining an ARM policy

- Activating an ARM policy
- Registering with ARM

Defining an ARM policy

Set up your ARM policy as follows:
- Define RESTART_GROUPs for each queue manager instance that also contain any CICS or IMS subsystems that connect to that queue manager instance. If you use a subsystem naming convention, you might be able to use the '?' and '*' wild-card characters in your element names to define RESTART_GROUPs with minimum definition effort.
- Specify TERMTYPE(ELEMTERM) for your channel initiators to indicate that they will be restarted only if the channel initiator has failed and the z/OS image has not failed.
- Specify TERMTYPE(ALLTERM) for your queue managers to indicate that they will be restarted if either the queue manager has failed or the z/OS image has failed.
- Specify RESTART_METHOD(BOTH, PERSIST) for both queue managers and channel initiators. This tells ARM to restart using the JCL it saved (after resolution of system symbols) during the last startup. It tells ARM to do this irrespective of whether the individual element failed, or the z/OS image failed.
- Accept the default values for all the other ARM policy options.

Activating an ARM policy

To start your automatic restart management policy, issue the following z/OS command:

```
SETXCF START,POLICY,TYPE=ARM,POLNAME= mypol
```

When the policy is started, all systems connected to the ARM couple data set use the same active policy.

Use the SETXCF STOP command to disable automatic restarts.

Registering with ARM

IBM MQ registers automatically as an *ARM element* during queue manager startup (subject to ARM availability). It deregisters during its shutdown phase, unless requested not to.

At startup, the queue manager determines whether ARM is available. If it is, IBM MQ registers using the name SYSMQMGR *ssid*, where *ssid* is the four character queue manager name, and SYSMQMGR is the element type.

The STOP QMGR MODE(QUIESCE) and STOP QMGR MODE(FORCE) commands deregister the queue manager from ARM (if it was registered with ARM at startup). This prevents ARM restarting this queue manager. The STOP QMGR MODE(RESTART) command does not deregister the queue manager from ARM, so it is eligible for immediate automatic restart.

Each channel initiator address space determines whether ARM is available, and if so registers with the element name SYSMQCH *ssid*, where *ssid* is the queue manager name, and SYSMQCH is the element type.

The channel initiator is always deregistered from ARM when it stops normally, and remains registered only if it ends abnormally. The channel initiator is always deregistered if the queue manager fails.

Using ARM in an IBM MQ network:

You can set up your queue manager so that the channel initiators and associated listeners are started automatically when the queue manager is restarted.

To ensure fully automatic queue manager restart on the same z/OS image for both LU 6.2 and TCP/IP communication protocols:

- Start your listeners automatically by adding the appropriate START LISTENER command to the CSQINPX data set.
- Start your channel initiator automatically by adding the appropriate START CHINIT command to the CSQINP2 data set.

For restarting a queue manager with TCP/IP or LU6.2, see

- "Restarting on a different z/OS image with TCP/IP"
- "Restarting on a different z/OS image with LU 6.2" on page 353

See Task 13: Customize the initialization input data sets for information about the CSQINP2 and CSQINPX data sets.

Restarting on a different z/OS image with TCP/IP

If you are using TCP/IP as your communication protocol, and you are using virtual IP addresses, you can configure these to recover on other z/OS images, allowing channels connecting to that queue manager to reconnect without any changes. Otherwise, you can reallocate a TCP/IP address after moving a queue manager to a different z/OS image only if you are using clusters or if you are connecting to a queue-sharing group using a WLM dynamic Domain Name System (DNS) logical group name.

- When using clustering
- When connecting to a queue-sharing group

When using clustering

z/OS ARM responds to a system failure by restarting the queue manager on a different z/OS image in the same sysplex; this system has a different TCP/IP address to the original z/OS image. The following explains how you can use IBM MQ clusters to reassign a queue manager's TCP/IP address after it has been moved by ARM restart to a different z/OS image.

When a client queue manager detects the queue manager failure (as a channel failure), it responds by reallocating suitable messages on its cluster transmission queue to a different server queue manager that hosts a different instance of the target cluster queue. However, it cannot reallocate messages that are bound to the original server by affinity constraints, or messages that are in doubt because the server queue manager failed during end-of-batch processing. To process these messages, do the following:

1. Allocate a different cluster-receiver channel name and a different TCP/IP port to each z/OS queue manager. Each queue manager needs a different port so that two systems can share a single TCP/IP stack on a z/OS image. One of these is the queue manager originally running on that z/OS image, and the other is the queue manager that ARM will restart on that z/OS image following a system failure. Configure each port on each z/OS image, so that ARM can restart any queue manager on any z/OS image.
2. Create a different channel initiator command input file (CSQINPX) for each queue manager and z/OS image combination, to be referenced during channel initiator startup.

   Each CSQINPX file must include a START LISTENER PORT(port) command specific to that queue manager, and an ALTER CHANNEL command for a cluster-receiver channel specific to that queue manager and z/OS image combination. The ALTER CHANNEL command needs to set the connection name to the TCP/IP name of the z/OS image on which it is restarted. It must include the port number specific to the restarted queue manager as part of the connection name.

The start-up JCL of each queue manager can have a fixed data set name for this CSQINPX file, and each z/OS image must have a different version of each CSQINPX file on a non-shared DASD volume.

If an ARM restart occurs, IBM MQ advertises the changed channel definition to the cluster repository, which in turn publishes it to all the client queue managers that have expressed an interest in the server queue manager.

The client queue manager treats the server queue manager failure as a channel failure, and tries to restart the failed channel. When the client queue manager learns the new server connection-name, the channel restart reconnects the client queue manager to the restarted server queue manager. The client queue manager can then resynchronize its messages, resolve any in-doubt messages on the client queue manager's transmission queue, and normal processing can continue.

When connecting to a queue-sharing group

When connecting to a queue-sharing group through a TCP/IP dynamic Domain Name System (DNS) logical group name, the connection name in your channel definition specifies the logical group name of your queue-sharing group, not the host name or IP address of a physical machine. When this channel starts, it connects to the dynamic DNS and is then connected to one of the queue managers in the queue-sharing group. This process is explained in Setting up communication for IBM MQ for z/OS using queue-sharing groups.

In the unlikely event of an image failure, one of the following occurs:

- The queue managers on the failing image de-register from the dynamic DNS running on your sysplex. The channel responds to the connection failure by entering RETRYING state and then connects to the dynamic DNS running on the sysplex. The dynamic DNS allocates the inbound request to one of the remaining members of the queue-sharing group that is still running on the remaining images.
- If no other queue manager in the queue-sharing group is active and ARM restarts the queue manager and channel initiator on a different image, the group listener registers with dynamic DNS from this new image. This means that the logical group name (from the connection name field of the channel) connects to the dynamic DNS and is then connected to the same queue manager, now running on a different image. No change was required to the channel definition.

For this type of recovery to occur, the following points must be noted:

- On z/OS, the dynamic DNS runs on one of the z/OS images in the sysplex. If this image were to fail, the dynamic DNS needs to be configured so that there is a secondary name server active in the sysplex, acting as an alternative to the primary name server. Information about primary and secondary dynamic DNS servers can be found in the *OS/390® SecureWay CS IP Configuration* manual.
- The TCP/IP group listener might have been started on a particular IP address that might not be available on this z/OS image. If so, the listener might need to be started on a different IP address on the new image. If you are using virtual IP addresses, you can configure these to recover on other z/OS images so that no change to the START LISTENER command is required.

Restarting on a different z/OS image with LU 6.2

If you use only LU 6.2 communication protocols, carry out the following procedure to enable network reconnect after automatic restart of a queue manager on a different z/OS image within the sysplex:

- Define each queue manager within the sysplex with a unique subsystem name.

- Define each channel initiator within the sysplex with a unique LUNAME. This is specified in both the queue manager attributes and in the START LISTENER command.

  Note: The LUNAME names an entry in the APPC side table, which in turn maps this to the actual LUNAME.
- Set up a shared APPC side table, which is referenced by each z/OS image within the sysplex. This should contain an entry for each channel initiator's LUNAME. See the *MVS Planning: APPC/MVS Management* manual for information about this.
- Set up an APPCPM *xx* member of SYS1.PARMLIB for each channel initiator within the sysplex to contain an LUADD to activate the APPC side table entry for that channel initiator. These members should be shared by each z/OS image. The appropriate SYS1.PARMLIB member is activated by a z/OS command SET APPC= *xx*, which is issued automatically during ARM restart of the queue manager (and its channel initiator) on a different z/OS image, as described in the following text.
- Use the LU62ARM queue manager attribute to specify the *xx* suffix of this SYS1.PARMLIB member for each channel initiator. This causes the channel initiator to issue the required z/OS command SET APPC= *xx* to activate its LUNAME.

Define your ARM policy so that it restarts the channel initiator only if it fails while its z/OS image stays up; the user ID associated with the XCFAS address space must be authorized to issue the IBM MQ command START CHINIT. Do not restart the channel initiator automatically if its z/OS image also fails, instead use commands in the CSQINP2 and CSQINPX data sets to start the channel initiator and listeners.

Recovering units of work manually

You can manually recover units of work CICS, IMS, RRS, or other queue managers in a queue-sharing group. You can use queue manager commands to display the status of the units of work associated with each connection to the queue manager.

This topic contains information about the following subjects:
- “Displaying connections and threads”
- “Recovering CICS units of recovery manually” on page 355
- “Recovering IMS units of recovery manually” on page 358
- “Recovering RRS units of recovery manually” on page 361
- “Recovering units of recovery on another queue manager in the queue-sharing group” on page 361

Displaying connections and threads

You can use the DISPLAY CONN command to get information about connections to queue managers and their associated units of work. You can display active units of work to see what is currently happening, or to see what needs to be terminated to allow the queue manager to shut down, and you can display unresolved units of work to help with recovery.

Active units of work

To display only active units of work, use

```
DISPLAY CONN(*) WHERE(UOWSTATE EQ ACTIVE)
```

Unresolved units of work

An unresolved unit of work, also known as an "in-doubt thread", is one that is in the second pass of the two-phase commit operation. Resources are held in IBM MQ on its behalf. To display unresolved units of work, use

```
DISPLAY CONN(*) WHERE(UOWSTATE EQ UNRESOLVED)
```

External intervention is needed to resolve the status of unresolved units of work. This might only involve starting the recovery coordinator (CICS, IMS, or RRS) or might involve more, as described in the following sections.

Recovering CICS units of recovery manually:

Use this topic to understand what happens when the CICS adapter restarts, and then explains how to deal with any unresolved units of recovery that arise.

What happens when the CICS adapter restarts

Whenever a connection is broken, the adapter has to go through a *restart phase* during the *reconnect process*. The restart phase resynchronizes resources. Resynchronization between CICS and IBM MQ enables in-doubt units of work to be identified and resolved.

Resynchronization can be caused by:
- An explicit request from the distributed queuing component
- An implicit request when a connection is made to IBM MQ

If the resynchronization is caused by connecting to IBM MQ, the sequence of events is:
1. The connection process retrieves a list of in-doubt units of work (UOW) IDs from IBM MQ.
2. The UOW IDs are displayed on the console in CSQC313I messages.
3. The UOW IDs are passed to CICS.
4. CICS initiates a resynchronization task (CRSY) for each in-doubt UOW ID.
5. The result of the task for each in-doubt UOW is displayed on the console.

You need to check the messages that are displayed during the connect process:

CSQC313I
Shows that a UOW is in doubt.

CSQC400I
Identifies the UOW and is followed by one of these messages:
- CSQC402I or CSQC403I shows that the UOW was resolved successfully (committed or backed out).
- CSQC404E, CSQC405E, CSQC406E, or CSQC407E shows that the UOW was not resolved.

CSQC409I
Shows that all UOWs were resolved successfully.

CSQC408I
Shows that not all UOWs were resolved successfully.

CSQC314I
Warns that UOW IDs highlighted with a * are not resolved automatically. These UOWs must be resolved explicitly by the distributed queuing component when it is restarted.

Figure 53 on page 356 shows an example set of restart messages displayed on the z/OS console.

Figure 53. Example restart messages

The total number of CSQC313I messages should equal the total number of CSQC402I plus CSQC403I messages. If the totals are not equal, there are UOWs that the connection process cannot resolve. Those UOWs that cannot be resolved are caused by problems with CICS (for example, a cold start) or with IBM MQ, or by distributing queuing. When these problems have been fixed, you can initiate another resynchronization by disconnecting and then reconnecting.

Alternatively, you can resolve each outstanding UOW yourself using the RESOLVE INDOUBT command and the UOW ID shown in message CSQC400I. You must then initiate a disconnect and a connect to clean up the *unit of recovery descriptors* in CICS. You need to know the correct outcome of the UOW to resolve UOWs manually.

All messages that are associated with unresolved UOWs are locked by IBM MQ and no Batch, TSO, or CICS task can access them.

If CICS fails and an emergency restart is necessary, *do not* vary the GENERIC APPLID of the CICS system. If you do and then reconnect to IBM MQ, data integrity with IBM MQ cannot be guaranteed. This is because IBM MQ treats the new instance of CICS as a different CICS (because the APPLID is different). In-doubt resolution is then based on the wrong CICS log.

How to resolve CICS units of recovery manually

If the adapter ends abnormally, CICS and IBM MQ build in-doubt lists either dynamically or during restart, depending on which subsystem caused the abend.

Note: If you use the DFH$INDB sample program to show units of work, you might find that it does not always show IBM MQ UOWs correctly.

When CICS connects to IBM MQ, there might be one or more units of recovery that have not been resolved.

One of the following messages is sent to the console:
- CSQC404E
- CSQC405E
- CSQC406E
- CSQC407E
- CSQC408I

For details of what these messages mean, see the CICS adapter and Bridge messages messages.

CICS retains details of units of recovery that were not resolved during connection startup. An entry is purged when it no longer appears on the list presented by IBM MQ.

Any units of recovery that CICS cannot resolve must be resolved manually using IBM MQ commands. This manual procedure is rarely used within an installation, because it is required only where operational errors or software problems have prevented automatic resolution. *Any inconsistencies found during in-doubt resolution must be investigated.*

To resolve the units of recovery:
1. Obtain a list of the units of recovery from IBM MQ using the following command:

```
+CSQ1  DISPLAY CONN( * ) WHERE(UOWSTATE EQ UNRESOLVED)
```

   You receive the following message:

```
CSQM201I +CSQ1 CSQMDRTC DISPLAY CONN DETAILS
CONN(BC85772CBE3E0001)
EXTCONN(C3E2D8C3C7D9F0F94040404040404040)
TYPE(CONN)
CONNOPTS(
MQCNO_STANDARD_BINDING
)
UOWLOGDA(2005-02-04)
UOWLOGTI(10.17.44)
UOWSTDA(2005-02-04)
UOWSTTI(10.17.44)
UOWSTATE(UNRESOLVED)
NID(IYRCSQ1 .BC8571519B60222D)
EXTURID(BC8571519B60222D)
QMURID(0000002BDA50)
URTYPE(CICS)
USERID(MQTEST)
APPLTAG(IYRCSQ1)
ASID(0000)
APPLTYPE(CICS)
TRANSID(GP02)
TASKNO(0000096)
END CONN DETAILS
```

For CICS connections, the NID consists of the CICS applid and a unique number provided by CICS at the time the syncpoint log entries are written. This unique number is stored in records written to both the CICS system log and the IBM MQ log at syncpoint processing time. This value is referred to in CICS as the *recovery token*.

2. Scan the CICS log for entries related to a particular unit of recovery.

   Look for a PREPARE record for the task-related installation where the recovery token field (JCSRMTKN) equals the value obtained from the network ID. The network ID is supplied by IBM MQ in the DISPLAY CONN command output.

   The PREPARE record in the CICS log for the units of recovery provides the CICS task number. All other entries on the log for this CICS task can be located using this number.

   You can use the CICS journal print utility DFHJUP when scanning the log. For details of using this program, see the *CICS Operations and Utilities Guide*.
3. Scan the IBM MQ log for records with the NID related to a particular unit of recovery. Then use the URID from this record to obtain the rest of the log records for this unit of recovery.

   When scanning the IBM MQ log, note that the IBM MQ startup message CSQJ001I provides the start RBA for this session.

   The print log records program (CSQ1LOGP) can be used for that purpose.
4. If you need to, do in-doubt resolution in IBM MQ.

   IBM MQ can be directed to take the recovery action for a unit of recovery using an IBM MQ RESOLVE INDOUBT command.

   To recover all threads associated with a specific *connection-name*, use the NID(*) option.

   The command produces one of the following messages showing whether the thread is committed or backed out:

```
CSQV414I +CSQ1 THREAD network-id COMMIT SCHEDULED
CSQV415I +CSQ1 THREAD network-id ABORT SCHEDULED
```

When performing in-doubt resolution, CICS and the adapter are not aware of the commands to IBM MQ to commit or back out units of recovery, because only IBM MQ resources are affected. However, CICS keeps details about the in-doubt threads that could not be resolved by IBM MQ. This information is purged either when the list presented is empty, or when the list does not include a unit of recovery of which CICS has details.

Recovering IMS units of recovery manually:

Use this topic to understand what happens when the IMS adapter restarts, and then explains how to deal with any unresolved units of recovery that arise.

What happens when the IMS adapter restarts

Whenever the connection to IBM MQ is restarted, either following a queue manager restart or an IMS /START SUBSYS command, IMS initiates the following resynchronization process:

1. IMS presents the list of unit of work (UOW) IDs that it believes are in doubt to the IBM MQ IMS adapter one at a time with a resolution parameter of Commit or Backout.
2. The IMS adapter passes the resolution request to IBM MQ and reports the result back to IMS.
3. Having processed all the IMS resolution requests, the IMS adapter gets from IBM MQ a list of all UOWs that IBM MQ still holds in doubt that were initiated by the IMS system. These are reported to the IMS master terminal in message CSQQ008I.

Note: While a UOW is in doubt, any associated IBM MQ message is locked by IBM MQ and is not available to any application.

How to resolve IMS units of recovery manually

When IMS connects to IBM MQ, IBM MQ might have one, or more in-doubt units of recovery that have not been resolved.

If IBM MQ has in-doubt units of recovery that IMS did not resolve, the following message is issued at the IMS master terminal:

```
CSQQ008I nn units of recovery are still in doubt in queue manager qmgr-name
```

If this message is issued, IMS was either cold-started or it was started with an incomplete log tape. This message can also be issued if IBM MQ or IMS terminates abnormally because of a software error or other subsystem failure.

After receiving the CSQQ008I message:
- The connection remains active.
- IMS applications can still access IBM MQ resources.
- Some IBM MQ resources remain locked out.

If the in-doubt thread is not resolved, IMS message queues can start to build up. If the IMS queues fill to capacity, IMS terminates. You must be aware of this potential difficulty, and you must monitor IMS until the in-doubt units of recovery are fully resolved.

Recovery procedure

Use the following procedure to recover the IMS units of work:

1. Force the IMS log closed, using /SWI OLDS, and then archive the IMS log. Use the utility, DFSERA10, to print the records from the previous IMS log tape. Type X'3730' log records indicate a phase-2 commit request and type X'38' log records indicate an abort request. Record the requested action for the last transaction in each dependent region.
2. Run the DL/I batch job to back out each PSB involved that has not reached a commit point. The process might take some time because transactions are still being processed. It might also lock up a number of records, which could affect the rest of the processing and the rest of the message queues.
3. Produce a list of the in-doubt units of recovery from IBM MQ using the following command:

```
+CSQ1 DISPLAY CONN(*) WHERE(UOWSTATE EQ UNRESOLVED)
```

You receive the following message:

```
CSQM201I +CSQ1 CSQMDRTC DISPLAY CONN DETAILS
CONN(BC45A794C4290001)
EXTCONN(C3E2D8C3E2C5C3F24040404040404040)
TYPE(CONN)
CONNOPTS(
MQCNO_STANDARD_BINDING
)
UOWLOGDA(2005-02-15)
UOWLOGTI(16.39.43)
UOWSTDA(2005-02-15)
UOWSTTI(16.39.43)
UOWSTATE(UNRESOLVED)
NID(IM8F  .BC45A794D3810344)
EXTURID(
0000052900000000
)
QMURID(00000354B76E)
URTYPE(IMS)
USERID(STCPI)
APPLTAG(IM8F)
ASID(0000)
APPLTYPE(IMS)
PSTID(0004)
PSBNAME(GP01MPP)
```

For IMS, the NID consists of the IMS connection name and a unique number provided by IMS. The value is referred to in IMS as the *recovery token*. For more information, see the *IMS Customization Guide*.

4. Compare the NIDs (IMSID plus OASN in hexadecimal) displayed in the DISPLAY THREAD messages with the OASNs (4 bytes decimal) shown in the DFSERA10 output. Decide whether to commit or back out.
5. Perform in-doubt resolution in IBM MQ with the RESOLVE INDOUBT command, as follows:

```
RESOLVE INDOUBT( connection-name )
ACTION(COMMIT|BACKOUT)
NID( network-id )
```

To recover all threads associated with *connection-name*, use the NID(*) option. The command results in one of the following messages to indicate whether the thread is committed or backed out:

```
CSQV414I  THREAD network-id COMMIT SCHEDULED
CSQV415I  THREAD network-id BACKOUT SCHEDULED
```

When performing in-doubt resolution, IMS and the adapter are not aware of the commands to IBM MQ to commit or back out in-doubt units of recovery because only IBM MQ resources are affected.

Recovering RRS units of recovery manually:

Use this topic to understand the how to determine if there are in-doubt RRS units of recovery, and how to manually resolve those units of recovery.

When RRS connects to IBM MQ, IBM MQ might have one, or more in-doubt units of recovery that have not been resolved. If IBM MQ has in-doubt units of recovery that RRS did not resolve, one of the following messages is issued at the z/OS console:

- CSQ3011I
- CSQ3013I
- CSQ3014I
- CSQ3016I

Both IBM MQ and RRS provide tools to display information about in-doubt units of recovery, and techniques for manually resolving them.

In IBM MQ, use the DISPLAY CONN command to display information about in-doubt IBM MQ threads. The output from the command includes RRS unit of recovery IDs for those IBM MQ threads that have RRS as a coordinator. This can be used to determine the outcome of the unit of recovery.

Use the RESOLVE INDOUBT command to resolve the IBM MQ in-doubt thread manually. This command can be used to either commit or back out the unit of recovery after you have determined what the correct decision is.

Recovering units of recovery on another queue manager in the queue-sharing group:

Use this topic to identify, and manually recover units of recovery on other queue managers in a queue-sharing group.

If a queue manager that is a member of a queue-sharing group fails and cannot be restarted, other queue managers in the group can perform peer recovery, and take over from it. However, the queue manager might have in-doubt units of recovery that cannot be resolved by peer recovery because the final disposition of that unit of recovery is known only to the failed queue manager. These units of recovery are resolved when the queue manager is eventually restarted, but until then, they remain in doubt.

This means that certain resources (for example, messages) might be locked, making them unavailable to other queue managers in the group. In this situation, you can use the DISPLAY THREAD command to display these units of work on the inactive queue manager. If you want to resolve these units of recovery manually to make the messages available to other queue managers in the group, you can use the RESOLVE INDOUBT command.

When you issue the DISPLAY THREAD command to display units of recovery that are in doubt, you can use the QMNAME keyword to specify the name of the inactive queue manager. For example, if you issue the following command:

```
+CSQ1 DISPLAY THREAD(*) TYPE(INDOUBT) QMNAME(QM01)
```

You receive the following messages:

```
CSQV436I +CSQ1 INDOUBT THREADS FOR QM01 -
NAME   THREAD-XREF    URID NID
USER1  000000000000000000000000 CSQ:0001.0
USER2  000000000000000000000000 CSQ:0002.0
DISPLAY THREAD REPORT COMPLETE
```

If the queue manager specified is active, IBM MQ does not return information about in-doubt threads, but issues the following message:

```
CSQV435I CANNOT USE QMNAME KEYWORD, QM01 IS ACTIVE
```

Use the IBM MQ command RESOLVE INDOUBT to resolve the in-doubt threads manually. Use the QMNAME keyword to specify the name of the inactive queue manager in the command.

This command can be used to commit or back out the unit of recovery. The command resolves the shared portion of the unit of recovery only; any local messages are unaffected and remain locked until the queue manager restarts, or reconnects to CICS, IMS, or RRS batch.

IBM MQ and IMS

IBM MQ provides two components to interface with IMS, the IBM MQ - IMS adapter, and the IBM MQ - IMS bridge. These components are commonly called the IMS adapter, and the IMS bridge.

Operating the IMS adapter

Use this topic to understand how to operate the IMS adapter, which connects IBM MQ to IMS systems.

Note: The IMS adapter does not incorporate any operations and control panels.

This topic contains the following sections:
- "Controlling IMS connections" on page 363
- "Connecting from the IMS control region" on page 363
- "Displaying in-doubt units of recovery" on page 365
- "Controlling IMS dependent region connections" on page 367
- "Disconnecting from IMS" on page 370
- "Controlling the IMS trigger monitor" on page 370

Controlling IMS connections:

Use this topic to understand the IMS operator commands which control and monitor the connection to IBM MQ.

IMS provides the following operator commands to control and monitor the connection to IBM MQ:

/CHANGE SUBSYS
: Deletes an in-doubt unit of recovery from IMS.

/DISPLAY OASN SUBSYS
: Displays outstanding recovery elements.

/DISPLAY SUBSYS
: Displays connection status and thread activity.

/START SUBSYS
: Connects the IMS control region to a queue manager.

/STOP SUBSYS
: Disconnects IMS from a queue manager.

/TRACE
: Controls the IMS trace.

For more information about these commands, see the *IMS/ESA® Operator's Reference* manual for the level of IMS that you are using.

IMS command responses are sent to the terminal from which the command was issued. Authorization to issue IMS commands is based on IMS security.

Connecting from the IMS control region:

Use this topic to understand the mechanisms available to connect from IMS to IBM MQ.

IMS makes one connection from its control region to each queue manager that uses IMS. IMS must be enabled to make the connection in one of these ways:
- Automatically during either:
  - A cold start initialization.
  - A warm start of IMS, if the IBM MQ connection was active when IMS was shut down.
- In response to the IMS command:

```
/START SUBSYS sysid
```

  where `sysid` is the queue manager name.

  The command can be issued regardless of whether the queue manager is active.

The connection is not made until the first MQ API call to the queue manager is made. Until that time, the IMS command /DIS SUBSYS shows the status as 'NOT CONN'.

The order in which you start IMS and the queue manager is not significant.

IMS cannot re-enable the connection to the queue manager automatically if the queue manager is stopped with a STOP QMGR command, the IMS command /STOP SUBSYS, or an abnormal end. Therefore, you must make the connection by using the IMS command /START SUBSYS.

Initializing the adapter and connecting to the queue manager

The adapter is a set of modules loaded into the IMS control and dependent regions, using the IMS external Subsystem Attach Facility.

This procedure initializes the adapter and connects to the queue manager:

1. Read the subsystem member (SSM) from IMS.PROCLIB. The SSM chosen is an IMS EXEC parameter. There is one entry in the member for each queue manager to which IMS can connect. Each entry contains control information about an IBM MQ adapter.
2. Load the IMS adapter.

   Note: IMS loads one copy of the adapter modules for each IBM MQ instance that is defined in the SSM member.
3. Attach the external subsystem task for IBM MQ.
4. Run the adapter with the CTL EXEC parameter (IMSID) as the connection name.

The process is the same whether the connection is part of initialization or a result of the IMS command /START SUBSYS.

If the queue manager is active when IMS tries to make the connection, the following messages are sent:

- to the z/OS console:

```
DFS3613I ESS TCB INITIALIZATION COMPLETE
```

- to the IMS master terminal:

```
CSQQ000I IMS/TM imsid connected to queue manager ssnm
```

When IMS tries to make the connection and *the queue manager is not active*, the following messages are sent to the IMS master terminal each time an application makes an MQI call:

```
CSQQ001I IMS/TM imsid not connected to queue manager ssnm.
Notify message accepted
DFS3607I MQM1   SUBSYSTEM ID EXIT FAILURE, FC = 0286, RC = 08,
JOBNAME = IMSEMPR1
```

If you get DFS3607I messages when you start the connection to IMS or on system startup, this indicates that the queue manager is not available. To prevent a large number of messages being generated, you must do one of the following:

1. Start the relevant queue manager.
2. Issue the IMS command:

```
/STOP SUBSYS
```

so that IMS does not expect to connect to the queue manager.

If you do neither, a DFS3607I message and the associated CSQQ001I message are issued each time a job is scheduled in the region and each time a connection request to the queue manager is made by an application.

Thread attachment

In an MPP or IFP region, IMS makes a thread connection when the first application program is scheduled into that region, even if that application program does not make an IBM MQ call. In a BMP region, the thread connection is made when the application makes its first IBM MQ call (**MQCONN** or **MQCONNX**). This thread is retained for the duration of the region or until the connection is stopped.

For both the message driven and non-message driven regions, the recovery thread cross-reference identifier, *Thread-xref*, associated with the thread is:

```
PSTid + PSBname
```

where:

PSTid Partition specification table region identifier

PSBname
Program specification block name

You can use connection IDs as unique identifiers in IBM MQ commands, in which case IBM MQ automatically inserts these IDs into any operator message that it generates.

Displaying in-doubt units of recovery:

You can display and in-doubt of units of recovery and attempt to recover them.

The operational steps used to list and recover in-doubt units of recovery in this topic are for relatively simple cases only. If the queue manager ends abnormally while connected to IMS, IMS might commit or back out work without IBM MQ being aware of it. When the queue manager restarts, that work is termed *in doubt*. A decision must be made about the status of the work.

To display a list of in-doubt units of recovery, issue the command:

```
+CSQ1  DISPLAY CONN(*) WHERE(UOWSTATE EQ UNRESOLVED)
```

IBM MQ responds with a message like the following:

For an explanation of the attributes in this message, see the description of the DISPLAY CONN

```

command.

Recovering in-doubt units of recovery

To recover in-doubt units of recovery, issue this command:

```
+CSQ1  RESOLVE INDOUBT( connection-name ) ACTION(COMMIT|BACKOUT)
NID( net-node.number )
```

where:

connection-name
    The IMS system ID.

ACTION
    Indicates whether to commit (COMMIT) or back out (BACKOUT) this unit of recovery.

net-node.number
    The associated net-node.number.

When you have issued the RESOLVE INDOUBT command, one of the following messages is displayed:

```
CSQV414I +CSQ1 THREAD network-id COMMIT SCHEDULED

CSQV415I +CSQ1 THREAD network-id BACKOUT SCHEDULED
```

Resolving residual recovery entries

At given times, IMS builds a list of residual recovery entries (RREs). RREs are units of recovery about which IBM MQ might be in doubt. They arise in several situations:

- If the queue manager is not active, IMS has RREs that cannot be resolved until the queue manager is active. These RREs are not a problem.
- If the queue manager is active and connected to IMS, and if IMS backs out the work that IBM MQ has committed, the IMS adapter issues message CSQQ010E. If the data in the two systems must be consistent, there is a problem. For information about resolving this problem, see "Recovering IMS units of recovery manually" on page 358.
- If the queue manager is active and connected to IMS, there might still be RREs even though no messages have informed you of this problem. After the IBM MQ connection to IMS has been established, you can issue the following IMS command to find out if there is a problem:

```
/DISPLAY OASN SUBSYS sysid
```

To purge the RRE, issue one of the following IMS commands:

```
/CHANGE SUBSYS sysid RESET
/CHANGE SUBSYS sysid RESET OASN nnnn
```

where *nnnn* is the originating application sequence number listed in response to your `+CSQ1` DISPLAY command. This is the schedule number of the program instance, giving its place in the sequence of invocations of that program since the last IMS cold start. IMS cannot have two in-doubt units of recovery with the same schedule number.

These commands reset the status of IMS ; they do not result in any communication with IBM MQ.

Controlling IMS dependent region connections:

You can control, monitor, and, when necessary, terminate connections between IMS and IBM MQ.

Controlling IMS dependent region connections involves the following activities:
- Connecting from dependent regions
- Region error options
- Monitoring the activity on connections
- Disconnecting from dependent regions

Connecting from dependent regions

The IMS adapter used in the control region is also loaded into dependent regions. A connection is made from each dependent region to IBM MQ. This connection is used to coordinate the commitment of IBM MQ and IMS work. To initialize and make the connection, IMS does the following:

1. Reads the subsystem member (SSM) from IMS.PROCLIB.

   A subsystem member can be specified on the dependent region EXEC parameter. If it is not specified, the control region SSM is used. If the region is never likely to connect to IBM MQ, to avoid loading the adapter, specify a member with no entries.
2. Loads the IBM MQ adapter.

   For a batch message program, the load is not done until the application issues its first messaging command. At that time, IMS tries to make the connection.

   For a message-processing program region or IMS fast-path region, the attempt is made when the region is initialized.

Region error options

If the queue manager is not active, or if resources are not available when the first messaging command is sent from application programs, the action taken depends on the error option specified on the SSM entry. The options are:

R The appropriate return code is sent to the application.

Q The application ends abnormally with abend code U3051. The input message is re-queued.

A The application ends abnormally with abend code U3047. The input message is discarded.

Monitoring the activity on connections

A thread is established from a dependent region when an application makes its first successful IBM MQ request. You can display information about connections and the applications currently using them by issuing the following command from IBM MQ:

```
+CSQ1 DISPLAY CONN(*) ALL
```

The command produces a message like the following:

```
CONN(BC45A794C4290001)
EXTCONN(C3E2D8C3C3E2D8F14040404040404040)
TYPE(CONN)
CONNOPTS(
MQCNO_STANDARD_BINDING
)
UOWLOGDA(2004-12-15)
UOWLOGTI(16.39.43)
UOWSTDA(2004-12-15)
UOWSTTI(16.39.43)
UOWSTATE(ACTIVE)
NID( )
EXTURID(
0000052900000000
)
QMURID(00000354B76E)
URTYPE(IMS)
USERID(STCPI)
APPLTAG(IM8F)
ASID(0049)
APPLTYPE(IMS)
PSTID(0004)
PSBNAME(GP01MPP)
```

For the control region, `thread-xref` is the special value CONTROL. For dependent regions, it is the PSTid concatenated with the PSBname. `auth-id` is either the user field from the job card, or the ID from the z/OS started procedures table.

For an explanation of the displayed list, see the description of message CSQV402I in the IBM MQ for z/OS messages, completion, and reason codes documentation.

IMS provides a display command to monitor the connection to IBM MQ. It shows which program is active on each dependent region connection, the LTERM user name, and the control region connection status. The command is:

```
/DISPLAY SUBSYS name
```

The status of the connection between IMS and IBM MQ is shown as one of:

```
CONNECTED
NOT CONNECTED
CONNECT IN PROGRESS
STOPPED
STOP IN PROGRESS
INVALID SUBSYSTEM NAME= name
SUBSYSTEM name NOT DEFINED BUT RECOVERY OUTSTANDING
```

The thread status from each dependent region is one of the following:

```
CONN
CONN, ACTIVE (includes LTERM of user)
```

Disconnecting from dependent regions

To change values in the SSM member of IMS.PROCLIB, you disconnect a dependent region. To do this, you must:

1. Issue the IMS command:

```
/STOP REGION
```

2. Update the SSM member.
3. Issue the IMS command:

```
/START REGION
```

Disconnecting from IMS:

The connection is ended when either IMS or the queue manager terminates. Alternatively, the IMS master terminal operator can explicitly break the connection.

To terminate the connection between IMS and IBM MQ, use the following IMS command:

```
/STOP SUBSYS sysid
```

The command sends the following message to the terminal that issued it, typically the master terminal operator (MTO):

```
DFS058I STOP COMMAND IN PROGRESS
```

The IMS command:

```
/START SUBSYS sysid
```

is required to reestablish the connection.

Note: The IMS command /STOP SUBSYS is not completed if an IMS trigger monitor is running.

Controlling the IMS trigger monitor:

You can use the CSQQTRMN transaction to stop, and start the IMS trigger monitor.

The IMS trigger monitor (the CSQQTRMN transaction) is described in the Setting up the IMS trigger monitor.

To control the IMS trigger monitor see:
- Starting CSQQTRMN
- Stopping CSQQTRMN

Starting CSQQTRMN
1. Start a batch-oriented BMP that runs the program CSQQTRMN for each initiation queue you want to monitor.
2. Modify your batch JCL to add a DDname of CSQQUT1 that points to a data set containing the following information:

```
QMGRNAME=q_manager_name    Comment: queue manager name
INITQUEUENAME=init_q_name   Comment: initiation queue name
LTERM=lterm          Comment: LTERM to remove error messages
CONSOLEMESSAGES=YES      Comment: Send error messages to console
```

   where:

`q_manager_name`	The name of the queue manager (if this is blank, the default nominated in CSQQDEFV is assumed)
`init_q_name`	The name of the initiation queue to be monitored
`lterm`	The IMS LTERM name for the destination of error messages (if this is blank, the default value is MASTER).
`CONSOLEMESSAGES=YES`	Requests that messages sent to the nominated IMS LTERM are also sent to the z/OS console. If this parameter is omitted or misspelled, the default is NOT to send messages to the console.

3. Add a DD name of CSQQUT2 if you want a printed report of the processing of CSQQUT1 input.

Note:
1. The data set CSQQUT1 is defined with LRECL=80. Other DCB information is taken from the data set. The DCB for data set CSQQUT2 is RECFM=VBA and LRECL=125.
2. You can put only one keyword on each record. The keyword value is delimited by the first blank following the keyword; this means that you can include comments. An asterisk in column 1 means that the whole input record is a comment.
3. If you misspell either of the `QMGRNAME` or `LTERM` keywords, CSQQTRMN uses the default for that keyword.
4. Ensure that the subsystem is started in IMS (by the /START SUBSYS command) before submitting the trigger monitor BMP job. If it is not started, your trigger monitor job terminates with abend code U3042.

Stopping CSQQTRMN

Once started, CSQQTRMN runs until either the connection between IBM MQ and IMS is broken due to one of the following events:
- the queue manager ending
- IMS ending

or a z/OS STOP **`jobname`** command is entered.

Controlling the IMS bridge

Use this topic to understand the IMS commands that you can use to control the IMS bridge.

There are no IBM MQ commands to control the IBM MQ-IMS bridge. However, you can stop messages being delivered to IMS in the following ways:
- For non-shared queues, by using the ALTER QLOCAL(xxx) GET(DISABLED) command for all bridge queues.
- For clustered queues, by using the SUSPEND QMGR CLUSTER(xxx) command. This is effective only when another queue manager is also hosting the clustered bridge queue.
- For clustered queues, by using the SUSPEND QMGR FACILITY(IMSBRIDGE) command. No further messages are sent to IMS, but the responses for any outstanding transactions are received from IMS.

  To start sending messages to IMS again, issue the RESUME QMGR FACILITY(IMSBRIDGE) command.

You can also use the MQSC command DISPLAY SYSTEM to display whether the bridge is suspended.

See MQSC commands for details of these commands.

For further information see:
- “Starting and stopping the IMS bridge” on page 372
- “Controlling IMS connections” on page 372

- Controlling bridge queues
- "Resynchronizing the IMS bridge" on page 373
- Working with tpipe names
- Deleting messages from IMS
- Deleting tpipes
- "IMS Transaction Expiration" on page 375

Starting and stopping the IMS bridge

Start the IBM MQ bridge by starting OTMA. Either use the IMS command:

```
/START OTMA
```

or start it automatically by specifying OTMA=YES in the IMS system parameters. If OTMA is already started, the bridge starts automatically when queue manager startup has completed. An IBM MQ event message is produced when OTMA is started.

Use the IMS command:

```
/STOP OTMA
```

to stop OTMA communication. When this command is issued, an IBM MQ event message is produced.

Controlling IMS connections

IMS provides these operator commands to control and monitor the connection to IBM MQ:

/DEQUEUE TMEMBER *tmember* **TPIPE** *tpipe*
: Removes messages from a Tpipe. Specify PURGE to remove all messages or PURGE1 to remove the first message only.

/DISPLAY OTMA
: Displays summary information about the OTMA server and clients, and client status.

/DISPLAY TMEMBER *name*
: Displays information about an OTMA client.

/DISPLAY TRACE TMEMBER *name*
: Displays information about what is being traced.

/SECURE OTMA
: Sets security options.

/START OTMA
: Enables communications through OTMA.

/START TMEMBER *tmember* **TPIPE** *tpipe*
: Starts the named Tpipe.

/STOP OTMA
: Stops communications through OTMA.

/STOP TMEMBER *tmember* **TPIPE** *tpipe*
: Stops the named Tpipe.

/TRACE
: Controls the IMS trace.

For more information about these commands, see the *IMS/ESA Operators Reference* manual for the level of IMS that you are using.

IMS command responses are sent to the terminal from which the command was issued. Authorization to issue IMS commands is based on IMS security.

Controlling bridge queues

To stop communicating with the queue manager with XCF member name *tmember* through the bridge, issue the following IMS command:

```
/STOP TMEMBER tmember TPIPE ALL
```

To resume communication, issue the following IMS command:

```
/START TMEMBER tmember TPIPE ALL
```

The Tpipes for a queue can be displayed using the MQ DISPLAY QUEUE command.

To stop communication with the queue manager on a single Tpipe, issue the following IMS command:

```
/STOP TMEMBER tmember TPIPE tpipe
```

One or two Tpipes are created for each active bridge queue, so issuing this command stops communication with the IBM MQ queue. To resume communication, use the following IMS command :

```
/START TMEMBER tmember TPIPE tpipe
```

Alternatively, you can alter the attributes of the IBM MQ queue to make it get inhibited.

Resynchronizing the IMS bridge

The IMS bridge is automatically restarted whenever the queue manager, IMS, or OTMA are restarted.

The first task undertaken by the IMS bridge is to resynchronize with IMS. This involves IBM MQ and IMS checking sequence numbers on every synchronized Tpipe. A synchronized Tpipe is used when persistent messages are sent to IMS from an IBM MQ - IMS bridge queue using commit mode zero (commit-then-send).

If the bridge cannot resynchronize with IMS, the IMS sense code is returned in message CSQ2023E and the connection to OTMA is stopped. If the bridge cannot resynchronize with an individual IMS Tpipe, the IMS sense code is returned in message CSQ2025E and the Tpipe is stopped. If a Tpipe has been cold started, the recoverable sequence numbers are automatically reset to 1.

If the bridge discovers mismatched sequence numbers when resynchronizing with a Tpipe, message CSQ2020E is issued. Use the IBM MQ command RESET TPIPE to initiate resynchronization with the IMS Tpipe. You need to provide the XCF group and member name, and the name of the Tpipe; this information is provided by the message.

You can also specify:

- A new recoverable sequence number to be set in the Tpipe for messages sent by IBM MQ, and to be set as the partner's receive sequence number. If you do not specify this, the partner's receive sequence number is set to the current IBM MQ send sequence number.
- A new recoverable sequence number to be set in the Tpipe for messages received by IBM MQ, and to be set as the partner's send sequence number. If you do not specify this, the partner's send sequence number is set to the current IBM MQ receive sequence number.

If there is an unresolved unit of recovery associated with the Tpipe, this is also notified in the message. Use the IBM MQ command RESET TPIPE to specify whether to commit the unit of recovery, or back it out. If you commit the unit of recovery, the batch of messages has already been sent to IMS, and is deleted from the bridge queue. If you back the unit of recovery out, the messages are returned to the bridge queue, to be later sent to IMS.

Commit mode 1 (send-then-commit) Tpipes are not synchronized.

Considerations for Commit mode 1 transactions

In IMS, commit mode 1 (CM1) transactions send their output replies before sync point.

A CM1 transaction might not be able to send its reply, for example because:
- The Tpipe on which the reply is to be sent is stopped
- OTMA is stopped
- The OTMA client (that is, the queue manager) has gone away
- The reply-to queue and dead-letter queue are unavailable

For these reasons, the IMS application sending the message pseudo-abends with code U0119. The IMS transaction and program are not stopped in this case.

These reasons often prevent messages being sent into IMS, as well as replies being delivered from IMS. A U0119 abend can occur if:
- The Tpipe, OTMA, or the queue manager is stopped while the message is in IMS
- IMS replies on a different Tpipe to the incoming message, and that Tpipe is stopped
- IMS replies to a different OTMA client, and that client is unavailable.

Whenever a U0119 abend occurs, both the incoming message to IMS and the reply messages to IBM MQ are lost. If the output of a CM0 transaction cannot be delivered for any of these reasons, it is queued on the Tpipe within IMS.

Working with tpipe names

Many of the commands used to control the IBM MQ - IMS bridge require the *tpipe* name. Use this topic to understand how you can find further details of the tpipe name.

You need *tpipe* names for many of the commands that control the IBM MQ - IMS bridge. You can get the tpipe names from DISPLAY QUEUE command and note the following points:
- tpipe names are assigned when a local queue is defined
- a local queue is given two tpipe names, one for sync and one for non-sync
- tpipe names will not be known to IMS until after some communication between IMS and IBM MQ specific to that particular local queue takes place
- For a tpipe to be available for use by the IBM MQ - IMS bridge its associated queue must be assigned to a Storage Class that has the correct XCF group and member name fields completed

Deleting messages from IMS

A message that is destined for IBM MQ through the IMS bridge can be deleted if the Tmember/Tpipe is stopped. To delete one message for the queue manager with XCF member name *tmember*, issue the following IMS command:

```
/DEQUEUE TMEMBER tmember TPIPE tpipe PURGE1
```

To delete all the messages on the Tpipe, issue the following IMS command:

```
/DEQUEUE TMEMBER tmember TPIPE tpipe PURGE
```

Deleting tpipes

You cannot delete IMS tpipes yourself. They are deleted by IMS at the following times:
- Synchronized tpipes are deleted when IMS is cold started.
- Non-synchronized tpipes are deleted when IMS is restarted.

IMS Transaction Expiration

An expiration time is associated with a transaction; any IBM MQ message can have an expiration time associated with it. The expiration interval is passed from the application, to IBM MQ, using the MQMD.Expiry field. The time is the duration of a message before it expires, expressed as a value in tenths of a second. An attempt to perform the MQGET of a message, later than it has expired, results in the message being removed from the queue and expiry processing performed. The expiration time decreases as a message flows between queue managers on an IBM MQ network. When an IMS message is passed across the IMS bridge to OTMA, the remaining message expiry time is passed to OTMA as a transaction expiration time.

If a transaction has an expiration time specified, OTMA expires the input transactions in three different places in IMS:
- input message receiving from XCF
- input message enqueuing time
- application GU time

No expiration is performed after the GU time.

The transaction EXPRTIME can be provided by:
- IMS transaction definition
- IMS OTMA message header
- IMS DFSINSX0 user exit
- IMS `CREATE` or `UPDATE TRAN` commands

IMS indicates that it has expired a transaction by abending a transaction with 0243, and issuing a message. The message issued is either DFS555I in the non-shared-queues environment, or DFS2224I in the shared-queues environment.

Operating IBM MQ Advanced Message Security

To enter commands for the IBM MQ Advanced Message Security address space, use the z/OS MODIFY command.

For example,

```
F qmgr AMSM, cmd
```

The following MODIFY commands are accepted:

Table 15. IBM MQ Advanced Message Security address space MODIFY commands

Command	Option	Description
DISPLAY		Display version information
REFRESH	KEYRING POLICY ALL	Refresh the key ring certificates, security policies, or both.
SMFAUDIT	SUCCESS FAILURE ALL	Set whether SMF auditing is required when AMS successfully protects/unprotects messages, when AMS fails to protect/unprotect messages, or both.
SMFTYPE	0 - 255	Set the SMF record type to be generated when AMS protects/unprotects messages. To disable SMF auditing specify a record type of 0.

Note: To specify an option it must be separated by a comma. For example:

```
F qmgrAMSM,REFRESH KEYRING
F qmgrAMSM,SMFAUDIT ALL
F qmgrAMSM,SMFTYPE 180
```

REFRESH command.

An application issuing an MQOPEN call will pick up the changes. Existing applications continue to use the options from when that application opened the queue. To pick up the changes, an application has to close and reopen the queue.

Security

Security is an important consideration for both developers of IBM MQ applications, and for system administrators configuring IBM MQ authorities.

Security overview

This collection of topics introduces the IBM MQ security concepts.

Security concepts and mechanisms, as they apply to any computer system, are presented first, followed by a discussion of those security mechanisms as they are implemented in IBM MQ.

Security concepts and mechanisms

This collection of topics describes aspects of security to consider in your IBM MQ installation.

The commonly accepted aspects of security are as follows:
- “Identification and authentication” on page 378
- “Authorization” on page 379
- “Auditing” on page 379
- “Confidentiality” on page 379
- “Data integrity” on page 379

Security mechanisms are technical tools and techniques that are used to implement security services. A mechanism might operate by itself, or with others, to provide a particular service. Examples of common security mechanisms are as follows:
- “Cryptography” on page 380
- “Message digests and digital signatures” on page 382
- “Digital certificates” on page 382
- “Public Key Infrastructure (PKI)” on page 387

When you are planning an IBM MQ implementation, consider which security mechanisms you require to implement those aspects of security that are important to you. For information about what to consider after you have read these topics, see “Planning for your security requirements” on page 443.

Related concepts:

"Working with SSL or TLS" on page 658
These topics give instructions for performing single tasks related to using SSL or TLS with IBM MQ.

Related information:

Connecting two queue managers using SSL or TLS

Identification and authentication

Identification is the ability to identify uniquely a user of a system or an application that is running in the system. *Authentication* is the ability to prove that a user or application is genuinely who that person or what that application claims to be.

For example, consider a user who logs on to a system by entering a user ID and password. The system uses the user ID to identify the user. The system authenticates the user at the time of logon by checking that the supplied password is correct.

Non-repudiation

The *non-repudiation* service can be viewed as an extension to the identification and authentication service. In general, non-repudiation applies when data is transmitted electronically; for example, an order to a stock broker to buy or sell stock, or an order to a bank to transfer funds from one account to another.

The overall goal of the non-repudiation service is to be able to prove that a particular message is associated with a particular individual.

The non-repudiation service can contain more than one component, where each component provides a different function. If the sender of a message ever denies sending it, the non-repudiation service with *proof of origin* can provide the receiver with undeniable evidence that the message was sent by that particular individual. If the receiver of a message ever denies receiving it, the non-repudiation service with *proof of delivery* can provide the sender with undeniable evidence that the message was received by that particular individual.

In practice, proof with virtually 100% certainty, or undeniable evidence, is a difficult goal. In the real world, nothing is fully secure. Managing security is more concerned with managing risk to a level that is acceptable to the business. In such an environment, a more realistic expectation of the non-repudiation service is to be able to provide evidence that is admissible, and supports your case, in a court of law.

Non-repudiation is a relevant security service in an IBM MQ environment because IBM MQ is a means of transmitting data electronically. For example, you might require contemporaneous evidence that a particular message was sent or received by an application associated with a particular individual.

IBM MQ with IBM MQ Advanced Message Security does not provide a non-repudiation service as part of its base function. However, this product documentation does contain suggestions on how you might provide your own non-repudiation service within an IBM MQ environment by writing your own exit programs.

Related concepts:

"Identification and authentication in IBM MQ" on page 395
In IBM MQ, you can implement identification and authentication using message context information and mutual authentication.

Authorization

Authorization protects critical resources in a system by limiting access only to authorized users and their applications. It prevents the unauthorized use of a resource or the use of a resource in an unauthorized manner.

Related concepts:

"Authorization in IBM MQ" on page 395
You can use authorization to limit what particular individuals or applications can do in your IBM MQ environment.

Auditing

Auditing is the process of recording and checking events to detect whether any unexpected or unauthorized activity has taken place, or whether any attempt has been made to perform such activity.

For more information on how you set up authorization, see "Planning authorization" on page 447 and the associated sub-topics.

Related concepts:

"Auditing in IBM MQ" on page 396
IBM MQ can issue event messages to record that unusual activity has taken place.

Confidentiality

The *confidentiality* service protects sensitive information from unauthorized disclosure.

When sensitive data is stored locally, access control mechanisms might be sufficient to protect it on the assumption that the data cannot be read if it cannot be accessed. If a greater level of security is required, the data can be encrypted.

Encrypt sensitive data when it is transmitted over a communications network, especially over an insecure network such as the Internet. In a networking environment, access control mechanisms are not effective against attempts to intercept the data, such as wiretapping.

Data integrity

The *data integrity* service detects whether there has been unauthorized modification of data.

There are two ways in which data might be altered: accidentally, through hardware and transmission errors, or because of a deliberate attack. Many hardware products and transmission protocols have mechanisms to detect and correct hardware and transmission errors. The purpose of the data integrity service is to detect a deliberate attack.

The data integrity service aims only to detect whether data has been modified. It does not aim to restore data to its original state if it has been modified.

Access control mechanisms can contribute to data integrity insofar as data cannot be modified if access is denied. But, as with confidentiality, access control mechanisms are not effective in a networking environment.

Cryptographic concepts

This collection of topics describes the concepts of cryptography applicable to IBM MQ.

The term *entity* is used to refer to a queue manager, an IBM MQ MQI client, an individual user, or any other system capable of exchanging messages.

Related concepts:

"Cryptography in IBM MQ" on page 397
IBM MQ provides cryptography by using the Secure sockets Layer (SSL) and Transport Security Layer (TLS) protocols.

Cryptography:

Cryptography is the process of converting between readable text, called *plaintext*, and an unreadable form, called *ciphertext*.

This occurs as follows:

1. The sender converts the plaintext message to ciphertext. This part of the process is called *encryption* (sometimes *encipherment*).
2. The ciphertext is transmitted to the receiver.
3. The receiver converts the ciphertext message back to its plaintext form. This part of the process is called *decryption* (sometimes *decipherment*).

The conversion involves a sequence of mathematical operations that change the appearance of the message during transmission but do not affect the content. Cryptographic techniques can ensure confidentiality and protect messages against unauthorized viewing (eavesdropping), because an encrypted message is not understandable. Digital signatures, which provide an assurance of message integrity, use encryption techniques. See "Digital signatures in SSL and TLS" on page 393 for more information.

Cryptographic techniques involve a general algorithm, made specific by the use of keys. There are two classes of algorithm:

- Those that require both parties to use the same secret key. Algorithms that use a shared key are known as *symmetric* algorithms. Figure 54 on page 381 illustrates symmetric key cryptography.
- Those that use one key for encryption and a different key for decryption. One of these must be kept secret but the other can be public. Algorithms that use public and private key pairs are known as *asymmetric* algorithms. Figure 55 on page 381 illustrates asymmetric key cryptography, which is also known as *public key cryptography*.

The encryption and decryption algorithms used can be public but the shared secret key and the private key must be kept secret.

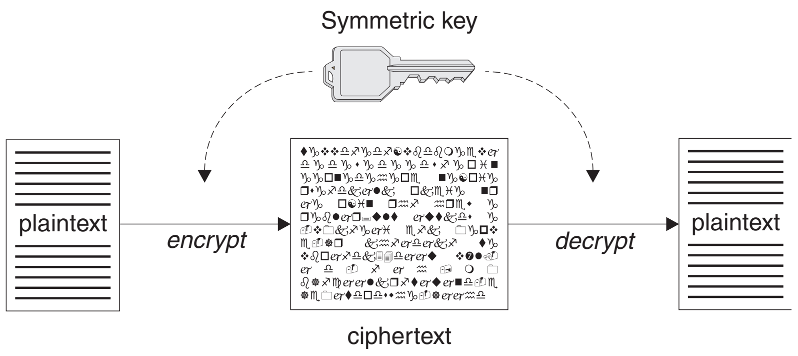

Figure 54. Symmetric key cryptography

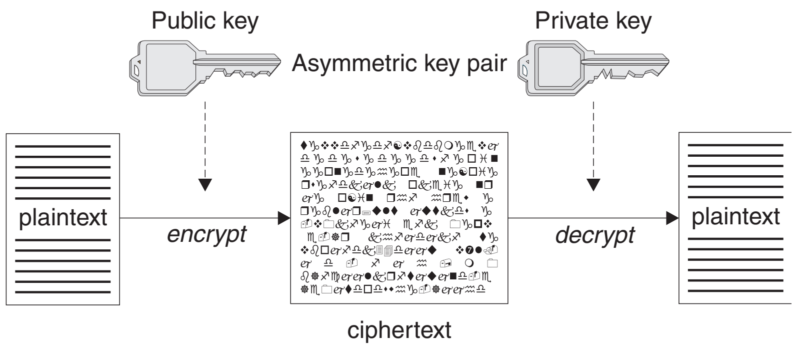

Figure 55. Asymmetric key cryptography

Figure 55 shows plaintext encrypted with the receiver's public key and decrypted with the receiver's private key. Only the intended receiver holds the private key for decrypting the ciphertext. Note that the sender can also encrypt messages with a private key, which allows anyone that holds the sender's public key to decrypt the message, with the assurance that the message must have come from the sender.

With asymmetric algorithms, messages are encrypted with either the public or the private key but can be decrypted only with the other key. Only the private key is secret, the public key can be known by anyone. With symmetric algorithms, the shared key must be known only to the two parties. This is called the *key distribution problem*. Asymmetric algorithms are slower but have the advantage that there is no key distribution problem.

Other terminology associated with cryptography is:

Strength
The strength of encryption is determined by the key size. Asymmetric algorithms require large keys, for example:

1024 bits	Low-strength asymmetric key
2048 bits	Medium-strength asymmetric key
4096 bits	High-strength asymmetric key

Symmetric keys are smaller: 256 bit keys give you strong encryption.

Block cipher algorithm
These algorithms encrypt data by blocks. For example, the RC2 algorithm from RSA Data Security Inc. uses blocks 8 bytes long. Block algorithms are typically slower than stream algorithms.

Stream cipher algorithm
These algorithms operate on each byte of data. Stream algorithms are typically faster than block algorithms.

Message digests and digital signatures:

A message digest is a fixed size numeric representation of the contents of a message. The message digest is computed by a hash function and can be encrypted, forming a digital signature.

The hash function used to compute a message digest must meet two criteria:
- It must be one way. It must not be possible to reverse the function to find the message corresponding to a particular message digest, other than by testing all possible messages.
- It must be computationally infeasible to find two messages that hash to the same digest.

The message digest is sent with the message itself. The receiver can generate a digest for the message and compare it with the digest of the sender. The integrity of the message is verified when the two message digests are the same. Any tampering with the message during transmission almost certainly results in a different message digest.

A message digest created using a secret symmetric key is known as a Message Authentication Code (MAC), because it can provide assurance that the message has not been modified.

The sender can also generate a message digest and then encrypt the digest using the private key of an asymmetric key pair, forming a digital signature. The signature must then be decrypted by the receiver, before comparing it with a locally generated digest.
Related concepts:
"Digital signatures in SSL and TLS" on page 393
A digital signature is formed by encrypting a representation of a message. The encryption uses the private key of the signatory and, for efficiency, usually operates on a message digest rather than the message itself.

Digital certificates:

Digital certificates protect against impersonation, certifying that a public key belongs to a specified entity. They are issued by a Certificate Authority.

Digital certificates provide protection against impersonation, because a digital certificate binds a public key to its owner, whether that owner is an individual, a queue manager, or some other entity. Digital certificates are also known as public key certificates, because they give you assurances about the ownership of a public key when you use an asymmetric key scheme. A digital certificate contains the public key for an entity and is a statement that the public key belongs to that entity:
- When the certificate is for an individual entity, the certificate is called a *personal certificate* or *user certificate*.
- When the certificate is for a Certificate Authority, the certificate is called a *CA certificate* or *signer certificate*.

If public keys are sent directly by their owner to another entity, there is a risk that the message could be intercepted and the public key substituted by another. This is known as a *man in the middle attack*. The solution to this problem is to exchange public keys through a trusted third party, giving you a strong assurance that the public key really belongs to the entity with which you are communicating. Instead of sending your public key directly, you ask the trusted third party to incorporate it into a digital certificate. The trusted third party that issues digital certificates is called a Certificate Authority (CA), as described in "Certificate Authorities" on page 384.

What is in a digital certificate:

Digital certificates contain specific pieces of information, as determined by the X.509 standard.

Digital certificates used by IBM MQ comply with the X.509 standard, which specifies the information that is required and the format for sending it. X.509 is the Authentication framework part of the X.500 series of standards.

Digital certificates contain at least the following information about the entity being certified:
- The owner's public key
- The owner's Distinguished Name
- The Distinguished Name of the CA that issued the certificate
- The date from which the certificate is valid
- The expiry date of the certificate
- The version number of the certificate data format as defined in X.509. The current version of the X.509 standard is Version 3, and most certificates conform to that version.
- A serial number. This is a unique identifier assigned by the CA which issued the certificate. The serial number is unique within the CA which issued the certificate: no two certificates signed by the same CA certificate have the same serial number.

An X.509 Version 2 certificate also contains an Issuer Identifier and a Subject Identifier, and an X.509 Version 3 certificate can contain a number of extensions. Some certificate extensions, such as the Basic Constraint extension, are *standard*, but others are implementation-specific. An extension can be *critical*, in which case a system must be able to recognize the field; if it does not recognize the field, it must reject the certificate. If an extension is not critical, the system can ignore it if it does not recognize it.

The digital signature in a personal certificate is generated using the private key of the CA which signed that certificate. Anyone who needs to verify the personal certificate can use the CA's public key to do so. The CA's certificate contains its public key.

Digital certificates do not contain your private key. You must keep your private key secret.

Requirements for personal certificates:

IBM MQ supports digital certificates that comply with the X.509 standard. It requires the client authentication option.

Because IBM MQ is a peer to peer system, it is viewed as client authentication in SSL terminology. Therefore, any personal certificate used for SSL authentication needs to allow a key usage of client authentication. Not all server certificates have this option enabled, so the certificate provider might need to enable client authentication on the root CA for the secure certificate.

In addition to the standards which specify the data format for a digital certificate, there are also standards for determining whether a certificate is valid. These standards have been updated over time in order to prevent certain types of security breach. For example, older X.509 version 1 and 2 certificates did not indicate whether the certificate could be legitimately used to sign other certificates. It was therefore possible for a malicious user to obtain a personal certificate from a legitimate source and create new certificates designed to impersonate other users.

When using X.509 version 3 certificates, the BasicConstraints and KeyUsage certificate extensions are used to specify which certificates can legitimately sign other certificates. The IETF RFC 5280 standard specifies a series of certificate validation rules which compliant application software must implement in order to prevent impersonation attacks. A set of certificate rules is known as a certificate validation policy.

For more information about certificate validation policies in IBM MQ, see “Certificate validation policies in IBM MQ” on page 418.

Certificate Authorities:

A Certificate Authority (CA) is a trusted third party that issues digital certificates to provide you with an assurance that the public key of an entity truly belongs to that entity.

The roles of a CA are:
- On receiving a request for a digital certificate, to verify the identity of the requestor before building, signing and returning the personal certificate
- To provide the CA's own public key in its CA certificate
- To publish lists of certificates that are no longer trusted in a Certificate Revocation List (CRL). For more information, see “Working with revoked certificates” on page 721
- To provide access to certificate revocation status by operating an OCSP responder server

Distinguished Names:

The Distinguished Name (DN) uniquely identifies an entity in an X.509 certificate.

Attention: Only the attributes in the following table can be used in an SSLPEER filter.

The following attribute types are commonly found in the DN:

SERIALNUMBER	Certificate serial number
MAIL	Email address
E	Email address (Deprecated in preference to MAIL)
UID or USERID	User identifier
CN	Common Name
T	Title
OU	Organizational Unit name
DC	Domain component
O	Organization name
STREET	Street / First line of address
L	Locality name
ST (or SP or S)	State or Province name
PC	Postal code / zip code
C	Country
UNSTRUCTUREDNAME	Host name
UNSTRUCTUREDADDRESS	IP address
DNQ	Distinguished name qualifier

The X.509 standard defines other attributes that do not typically form part of the DN but can provide optional extensions to the digital certificate.

The X.509 standard provides for a DN to be specified in a string format. For example:

```
CN=John Smith, OU=Test, O=IBM, C=GB
```

The Common Name (CN) can describe an individual user or any other entity, for example a web server.

The DN can contain multiple OU and DC attributes. Only one instance of each of the other attributes is permitted. The order of the OU entries is significant: the order specifies a hierarchy of Organizational Unit names, with the highest-level unit first. The order of the DC entries is also significant.

IBM MQ tolerates certain malformed DNs. For more information, see IBM MQ rules for SSLPEER values.

Related concepts:
“What is in a digital certificate” on page 383
Digital certificates contain specific pieces of information, as determined by the X.509 standard.

Obtaining personal certificates from a certificate authority:

You can obtain a certificate from a trusted external certificate authority (CA).

You obtain a digital certificate by sending information to a CA, in the form of a certificate request. The X.509 standard defines a format for this information, but some CAs have their own format. Certificate requests are typically generated by the certificate management tool your system uses; for example:

- distributed IBM i Te iKeyman tool on UNIX, Linux, and Windows systems
- z/OS RACF on z/OS.

The information contains your Distinguished Name and your public key. When your certificate management tool generates your certificate request, it also generates your private key, which you must keep secure. Never distribute your private key.

When the CA receives your request, the authority verifies your identity before building the certificate and returning it to you as a personal certificate.

Figure 56 illustrates the process of obtaining a digital certificate from a CA.

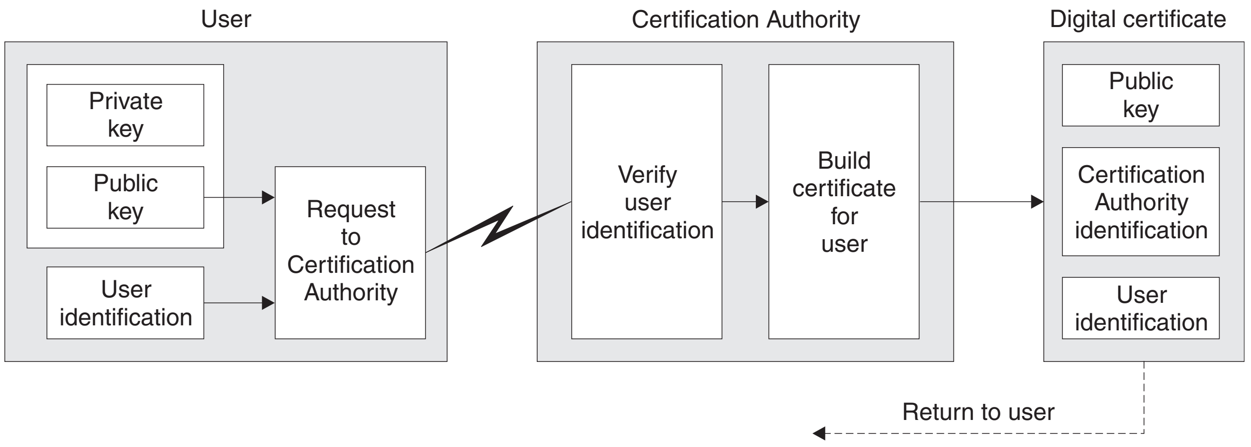

Figure 56. Obtaining a digital certificate

In the diagram:
- "User identification" includes your Subject Distinguished Name.
- "Certification Authority identification" includes the Distinguished Name of the CA that is issuing the certificate.

Digital certificates contain additional fields other than those shown in the diagram. For more information about the other fields in a digital certificate, see “What is in a digital certificate” on page 383.

How certificate chains work:

When you receive the certificate for another entity, you might need to use a *certificate chain* to obtain the *root CA* certificate.

The certificate chain, also known as the *certification path*, is a list of certificates used to authenticate an entity. The chain, or path, begins with the certificate of that entity, and each certificate in the chain is signed by the entity identified by the next certificate in the chain. The chain terminates with a root CA certificate. The root CA certificate is always signed by the certificate authority (CA) itself. The signatures of all certificates in the chain must be verified until the root CA certificate is reached.

Figure 57 illustrates a certification path from the certificate owner to the root CA, where the chain of trust begins.

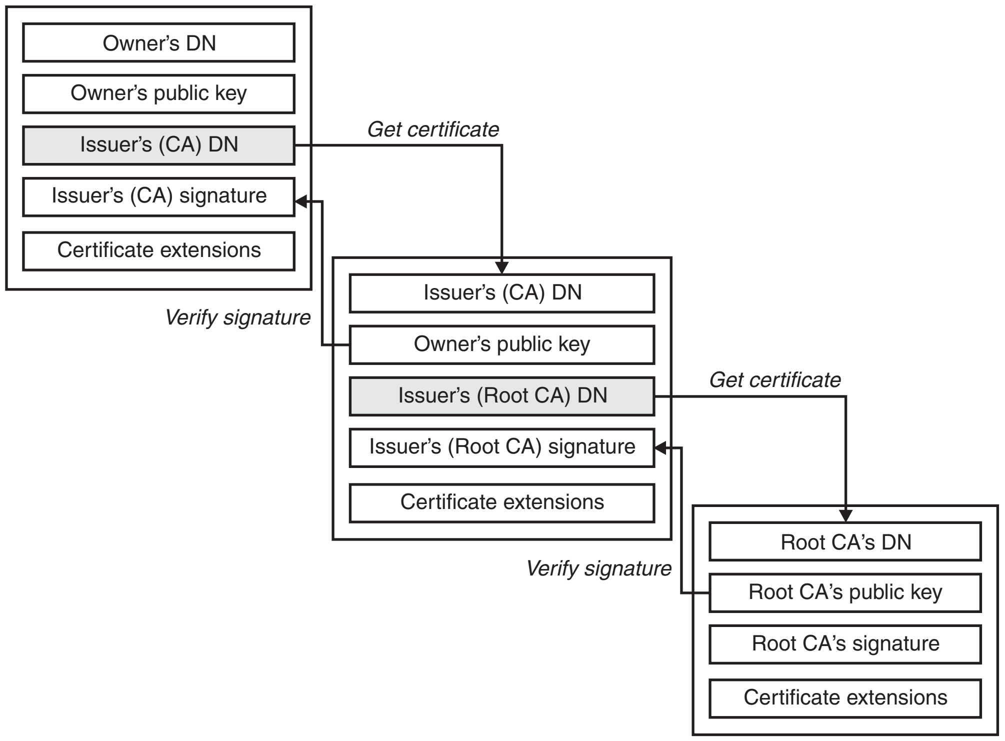

Figure 57. Chain of trust

Each certificate can contain one or more extensions. A certificate belonging to a CA typically contains a BasicConstraints extension with the isCA flag set to indicate that it is allowed to sign other certificates.

When certificates are no longer valid:

Digital certificates can expire or be revoked.

Digital certificates are issued for a fixed period and are not valid after their expiry date.

Certificates can be revoked for various reasons, including:
- The owner has moved to a different organization.
- The private key is no longer secret.

IBM MQ can check whether a certificate is revoked by sending a request to an Online Certificate Status Protocol (OCSP) responder (on UNIX, Linux and Windows systems only). Alternatively, they can access a Certificate Revocation List (CRL) on an LDAP server. The OCSP revocation and CRL information is published by a Certificate Authority. For more information, see "Working with revoked certificates" on page 721.

Public Key Infrastructure (PKI):

A Public Key Infrastructure (PKI) is a system of facilities, policies, and services that supports the use of public key cryptography for authenticating the parties involved in a transaction.

There is no single standard that defines the components of a Public Key Infrastructure, but a PKI typically comprises certificate authorities (CAs) and Registration Authorities (RAs). CAs provide the following services::
- Issuing digital certificates
- Validating digital certificates
- Revoking digital certificates
- Distributing public keys

The X.509 standards provide the basis for the industry standard Public Key Infrastructure.

Refer to "Digital certificates" on page 382 for more information about digital certificates and certificate authorities (CAs). RAs verify the information provided when digital certificates are requested. If the RA verifies that information, the CA can issue a digital certificate to the requester.

A PKI might also provide tools for managing digital certificates and public keys. A PKI is sometimes described as a *trust hierarchy* for managing digital certificates, but most definitions include additional services. Some definitions include encryption and digital signature services, but these services are not essential to the operation of a PKI.

Cryptographic security protocols: SSL and TLS

Cryptographic protocols provide secure connections, enabling two parties to communicate with privacy and data integrity. The Transport Layer Security (TLS) protocol evolved from that of the Secure Sockets Layer (SSL). IBM MQ supports both SSL and TLS.

The primary goals of both protocols is to provide confidentiality, (sometimes referred to as *privacy*), data integrity, identification, and authentication using digital certificates.

Although the two protocols are similar, the differences are sufficiently significant that SSL 3.0 and the various versions of TLS do not interoperate.

Related concepts:

"SSL and TLS security protocols in IBM MQ" on page 397
IBM MQ supports both the Transport Layer Security (TLS) and the Secure Sockets Layer (SSL) protocols to provide link level security for message channels and MQI channels.

Secure Sockets Layer (SSL) and Transport Layer Security (TLS) concepts:

The SSL and TLS protocols enable two parties to identify and authenticate each other and communicate with confidentiality and data integrity. The TLS protocol evolved from the Netscape SSL 3.0 protocol but TLS and SSL do not interoperate.

The SSL and TLS protocols provide communications security over the internet, and allow client/server applications to communicate in a way that is confidential and reliable. The protocols have two layers: a Record Protocol and a Handshake Protocol, and these are layered above a transport protocol such as TCP/IP. They both use asymmetric and symmetric cryptography techniques.

An SSL or TLS connection is initiated by an application, which becomes the SSL or TLS client. The application which receives the connection becomes the SSL or TLS server. Every new session begins with a handshake, as defined by the SSL or TLS protocols.

A full list of CipherSpecs supported by IBM MQ is provided at "Enabling CipherSpecs" on page 797.

For more information about the SSL protocol, see the information provided at http://www.mozilla.org/projects/security/pki/nss/ssl/draft302.txt. For more information about the TLS protocol, see the information provided by the TLS Working Group on the website of the Internet Engineering Task Force at http://www.ietf.org

An overview of the SSL or TLS handshake:

The SSL or TLS handshake enables the SSL or TLS client and server to establish the secret keys with which they communicate.

This section provides a summary of the steps that enable the SSL or TLS client and server to communicate with each other:

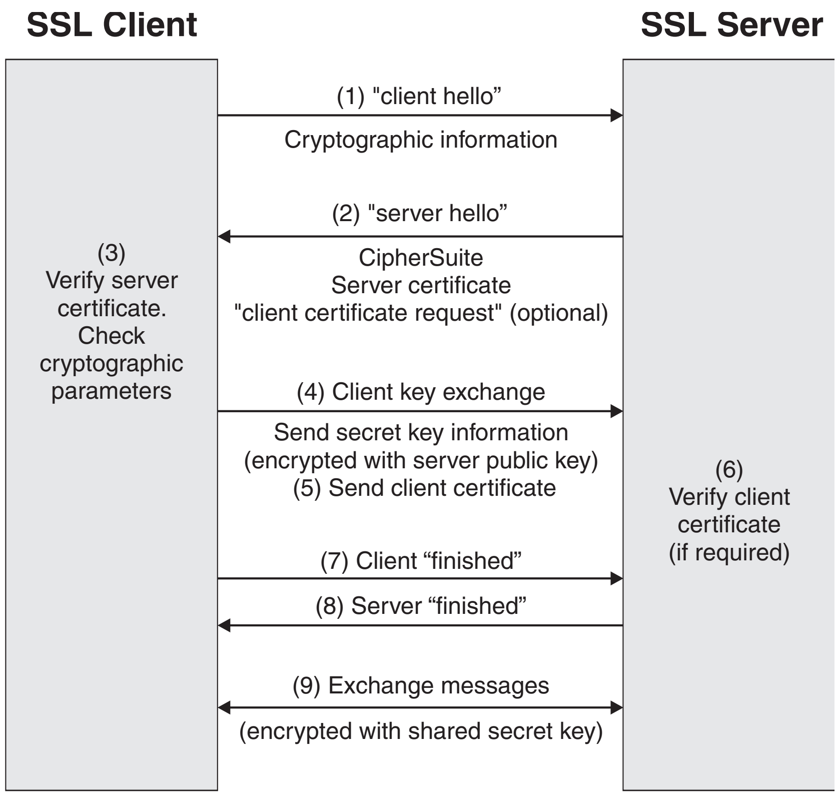
- Agree on the version of the protocol to use.
- Select cryptographic algorithms.
- Authenticate each other by exchanging and validating digital certificates.
- Use asymmetric encryption techniques to generate a shared secret key, which avoids the key distribution problem. SSL or TLS then uses the shared key for the symmetric encryption of messages, which is faster than asymmetric encryption.

For more information about cryptographic algorithms and digital certificates, refer to the related information.

This section does not attempt to provide full details of the messages exchanged during the SSL handshake. In overview, the steps involved in the SSL handshake are as follows:

1. The SSL or TLS client sends a “client hello” message that lists cryptographic information such as the SSL or TLS version and, in the client's order of preference, the CipherSuites supported by the client. The message also contains a random byte string that is used in subsequent computations. The protocol allows for the “client hello” to include the data compression methods supported by the client.
2. The SSL or TLS server responds with a “server hello” message that contains the CipherSuite chosen by the server from the list provided by the client, the session ID, and another random byte string. The server also sends its digital certificate. If the server requires a digital certificate for client authentication, the server sends a “client certificate request” that includes a list of the types of certificates supported and the Distinguished Names of acceptable Certification Authorities (CAs).
3. The SSL or TLS client verifies the server's digital certificate. For more information, see “How SSL and TLS provide identification, authentication, confidentiality, and integrity” on page 390.
4. The SSL or TLS client sends the random byte string that enables both the client and the server to compute the secret key to be used for encrypting subsequent message data. The random byte string itself is encrypted with the server's public key.
5. If the SSL or TLS server sent a “client certificate request”, the client sends a random byte string encrypted with the client's private key, together with the client's digital certificate, or a “no digital certificate alert”. This alert is only a warning, but with some implementations the handshake fails if client authentication is mandatory.
6. The SSL or TLS server verifies the client's certificate. For more information, see “How SSL and TLS provide identification, authentication, confidentiality, and integrity” on page 390.
7. The SSL or TLS client sends the server a “finished” message, which is encrypted with the secret key, indicating that the client part of the handshake is complete.
8. The SSL or TLS server sends the client a “finished” message, which is encrypted with the secret key, indicating that the server part of the handshake is complete.
9. For the duration of the SSL or TLS session, the server and client can now exchange messages that are symmetrically encrypted with the shared secret key.

Figure 58 on page 390 illustrates the SSL or TLS handshake.



SSL Client
SSL Server
(1) "client hello”
Cryptographic information
(2) "server hello”
CipherSuite
Server certificate
"client certificate request" (optional)
(3) Verify server certificate. Check cryptographic parameters
(4) Client key exchange
Send secret key information (encrypted with server public key)
(5) Send client certificate
(6) Verify client certificate (if required)
(7) Client “finished”
(8) Server “finished”
(9) Exchange messages
(encrypted with shared secret key)

Figure 58. Overview of the SSL or TLS handshake

How SSL and TLS provide identification, authentication, confidentiality, and integrity:

During both client and server authentication there is a step that requires data to be encrypted with one of the keys in an asymmetric key pair and decrypted with the other key of the pair. A message digest is used to provide integrity.

How SSL and TLS provide authentication

For server authentication, the client uses the server's public key to encrypt the data that is used to compute the secret key. The server can generate the secret key only if it can decrypt that data with the correct private key.

For client authentication, the server uses the public key in the client certificate to decrypt the data the client sends during step 5 on page 389 of the handshake. The exchange of finished messages that are encrypted with the secret key (steps 7 on page 389 and 8 on page 389 in the overview) confirms that authentication is complete.

If any of the authentication steps fail, the handshake fails and the session terminates.

The exchange of digital certificates during the SSLor TLS handshake is part of the authentication process. For more information about how certificates provide protection against impersonation, refer to the related information. The certificates required are as follows, where CA `X` issues the certificate to the SSL or TLS client, and CA `Y` issues the certificate to the SSL or TLS server:

For server authentication only, the SSL or TLS server needs:
- The personal certificate issued to the server by CA `Y`
- The server's private key

and the SSL or TLS client needs:
- The CA certificate for CA Y

If the SSL or TLS server requires client authentication, the server verifies the client's identity by verifying the client's digital certificate with the public key for the CA that issued the personal certificate to the client, in this case CA X. For both server and client authentication, the server needs:
- The personal certificate issued to the server by CA Y
- The server's private key
- The CA certificate for CA X

and the client needs:
- The personal certificate issued to the client by CA X
- The client's private key
- The CA certificate for CA Y

Both the SSL or TLS server and client might need other CA certificates to form a certificate chain to the root CA certificate. For more information about certificate chains, refer to the related information.

What happens during certificate verification

As noted in steps 3 on page 389 and 6 on page 389 of the overview, the SSL or TLS client verifies the server's certificate, and the SSL or TLS server verifies the client's certificate. There are four aspects to this verification:
1. The digital signature is checked (see "Digital signatures in SSL and TLS" on page 393).
2. The certificate chain is checked; you should have intermediate CA certificates (see "How certificate chains work" on page 386).
3. The expiry and activation dates and the validity period are checked.
4. The revocation status of the certificate is checked (see "Working with revoked certificates" on page 721).

Secret key reset

During an SSL or TLS handshake a *secret key* is generated to encrypt data between the SSL or TLS client and server. The secret key is used in a mathematical formula that is applied to the data to transform plaintext into unreadable ciphertext, and ciphertext into plaintext.

The secret key is generated from the random text sent as part of the handshake and is used to encrypt plaintext into ciphertext. The secret key is also used in the MAC (Message Authentication Code) algorithm, which is used to determine whether a message has been altered. See "Message digests and digital signatures" on page 382 for more information.

If the secret key is discovered, the plaintext of a message could be deciphered from the ciphertext, or the message digest could be calculated, allowing messages to be altered without detection. Even for a complex algorithm, the plaintext can eventually be discovered by applying every possible mathematical transformation to the ciphertext. To minimize the amount of data that can be deciphered or altered if the secret key is broken, the secret key can be renegotiated periodically. When the secret key has been renegotiated, the previous secret key can no longer be used to decrypt data encrypted with the new secret key.

How SSL and TLS provide confidentiality

SSL and TLS use a combination of symmetric and asymmetric encryption to ensure message privacy. During the SSL or TLS handshake, the SSL or TLS client and server agree an encryption algorithm and a shared secret key to be used for one session only. All messages transmitted between the SSL or TLS client and server are encrypted using that algorithm and key, ensuring that the message remains private even if it is intercepted. SSL supports a wide range of cryptographic algorithms. Because SSL and TLS use asymmetric encryption when transporting the shared secret key, there is no key distribution problem. For more information about encryption techniques, refer to “Cryptography” on page 380.

How SSL and TLS provide integrity

SSL and TLS provide data integrity by calculating a message digest. For more information, refer to “Data integrity of messages” on page 809.

Use of SSL or TLS does ensure data integrity, provided that the CipherSpec in your channel definition uses a hash algorithm as described in the table in “Enabling CipherSpecs” on page 797.

In particular, if data integrity is a concern, you should avoid choosing a CipherSpec whose hash algorithm is listed as "None". Use of MD5 is also strongly discouraged as this is now very old and no longer secure for most practical purposes.

CipherSpecs and CipherSuites:

Cryptographic security protocols must agree on the algorithms used by a secure connection. CipherSpecs and CipherSuites define specific combinations of algorithms.

A CipherSpec identifies a combination of encryption algorithm and Message Authentication Code (MAC) algorithm. Both ends of a TLS, or SSL, connection must agree on the same CipherSpec to be able to communicate.

From IBM MQ Version 8.0.0, Fix Pack 2 the SSLv3 protocol and the use of some IBM MQ CipherSpecs is deprecated. For more information, see Deprecation: SSLv3 protocol.

Important: When dealing with IBM MQ channels, you use a CipherSpec. When dealing with Java channels, JMS channels, or MQTT channels you specify a CipherSuite.

For more information about CipherSpecs, see “Enabling CipherSpecs” on page 797.

A CipherSuite is a suite of cryptographic algorithms used by a TLS or SSL connection. A suite comprises three distinct algorithms:
- The key exchange and authentication algorithm, used during the handshake
- The encryption algorithm, used to encipher the data
- The MAC (Message Authentication Code) algorithm, used to generate the message digest

There are several options for each component of the suite, but only certain combinations are valid when specified for a TLS or SSL connection. The name of a valid CipherSuite defines the combination of algorithms used. For example, the CipherSuite SSL_RSA_WITH_RC4_128_MD5 specifies:
- The RSA key exchange and authentication algorithm
- The RC4 encryption algorithm, using a 128-bit key
- The MD5 MAC algorithm

Several algorithms are available for key exchange and authentication, but the RSA algorithm is currently the most widely used. There is more variety in the encryption algorithms and MAC algorithms that are used.

Digital signatures in SSL and TLS:

A digital signature is formed by encrypting a representation of a message. The encryption uses the private key of the signatory and, for efficiency, usually operates on a message digest rather than the message itself.

Digital signatures vary with the data being signed, unlike handwritten signatures, which do not depend on the content of the document being signed. If two different messages are signed digitally by the same entity, the two signatures differ, but both signatures can be verified with the same public key, that is, the public key of the entity that signed the messages.

The steps of the digital signature process are as follows:

1. The sender computes a message digest and then encrypts the digest using the sender's private key, forming the digital signature.
2. The sender transmits the digital signature with the message.
3. The receiver decrypts the digital signature using the sender's public key, regenerating the sender's message digest.
4. The receiver computes a message digest from the message data received and verifies that the two digests are the same.

Figure 59 illustrates this process.

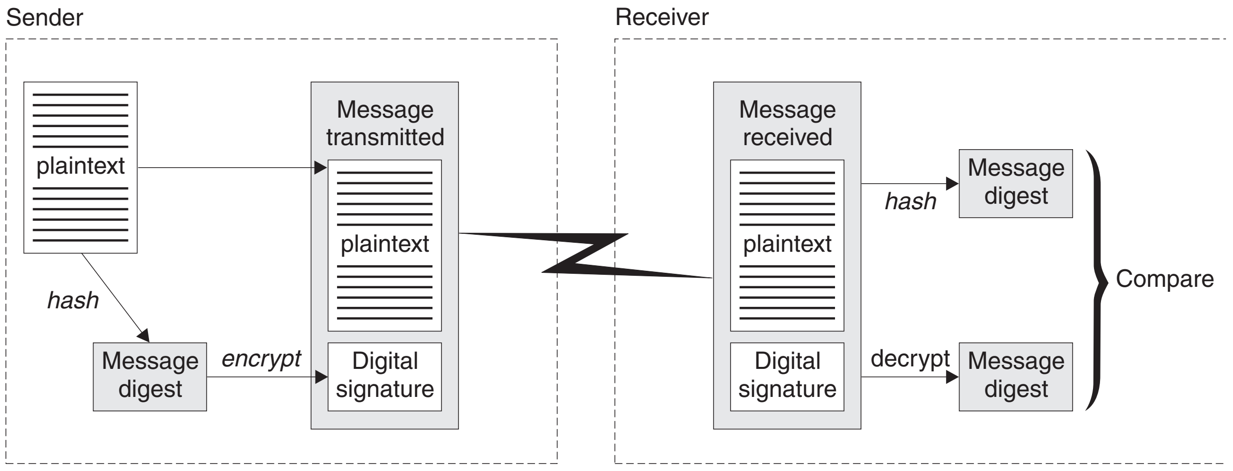


Figure 59. The digital signature process

If the digital signature is verified, the receiver knows that:

- The message has not been modified during transmission.
- The message was sent by the entity that claims to have sent it.

Digital signatures are part of integrity and authentication services. Digital signatures also provide proof of origin. Only the sender knows the private key, which provides strong evidence that the sender is the originator of the message.

Note: You can also encrypt the message itself, which protects the confidentiality of the information in the message.

Federal Information Processing Standards:

The US government produces technical advice on IT systems and security, including data encryption. The National Institute for Standards and Technology (NIST) is an important body concerned with IT systems and security. NIST produces recommendations and standards, including the Federal Information Processing Standards (FIPS).

A significant one of these standards is FIPS 140-2, which requires the use of strong cryptographic algorithms. FIPS 140-2 also specifies requirements for hashing algorithms to be used to protect packets against modification in transit.

IBM MQ provides FIPS 140-2 support when it has been configured to do so.

Over time, analysts develop attacks against existing encryption and hashing algorithms. New algorithms are adopted to resist those attacks. FIPS 140-2 is periodically updated to take account of these changes.

Related concepts:
"National Security Agency (NSA) Suite B Cryptography"
The government of the Unites States of America produces technical advice on IT systems and security, including data encryption. The US National Security Agency (NSA) recommends a set of interoperable cryptographic algorithms in its Suite B standard.

National Security Agency (NSA) Suite B Cryptography:

The government of the Unites States of America produces technical advice on IT systems and security, including data encryption. The US National Security Agency (NSA) recommends a set of interoperable cryptographic algorithms in its Suite B standard.

The Suite B standard specifies a mode of operation in which only a specific set of secure cryptographic algorithms are used. The Suite B standard specifies:
- The encryption algorithm (AES)
- The key exchange algorithm (Elliptic Curve Diffie-Hellman, also known as ECDH)
- The digital signature algorithm (Elliptic Curve Digital Signature Algorithm, also known as ECDSA)
- The hashing algorithms (SHA-256 or SHA-384)

Additionally, the IETF RFC 6460 standard specifies Suite B compliant profiles which define the detailed application configuration and behavior necessary to comply with the Suite B standard. It defines two profiles:
1. A Suite B compliant profile for use with TLS version 1.2. When configured for Suite B compliant operation, only the restricted set of cryptographic algorithms listed are used.
2. A transitional profile for use with TLS version 1.0 or TLS version 1.1. This profile enables interoperability with non-Suite B compliant servers. When configured for Suite B transitional operation, additional encryption and hashing algorithms may be used.

The Suite B standard is conceptually similar to FIPS 140-2, because it restricts the set of enabled cryptographic algorithms in order to provide an assured level of security.

On Windows, UNIX and Linux systems, IBM MQ, can be configured to conform to the Suite B compliant TLS 1.2 profile, but does not support the Suite B transitional profile. For further information, see "NSA Suite B Cryptography in IBM MQ" on page 415.

IBM MQ security mechanisms

This collection of topics explains how you can implement the various security concepts in IBM MQ.

IBM MQ provides mechanisms to implement all the security concepts introduced in "Security concepts and mechanisms" on page 377. These are discussed in more detail in the following sections.

Identification and authentication in IBM MQ

In IBM MQ, you can implement identification and authentication using message context information and mutual authentication.

Here are some examples of the identification and authentication in an IBM MQ environment:

- Every message can contain *message context* information. This information is held in the message descriptor. It can be generated by the queue manager when a message is put on a queue by an application. Alternatively, the application can supply the information if the user ID associated with the application is authorized to do so.

  The context information in a message allows the receiving application to find out about the originator of the message. It contains, for example, the name of the application that put the message and the user ID associated with the application.
- When a message channel starts, it is possible for the message channel agent (MCA) at each end of the channel to authenticate its partner. This technique is known as *mutual authentication*. For the sending MCA, it provides assurance that the partner it is about to send messages to is genuine. For the receiving MCA, there is a similar assurance that it is about to receive messages from a genuine partner.

Related concepts:

"Identification and authentication" on page 378
Identification is the ability to identify uniquely a user of a system or an application that is running in the system. *Authentication* is the ability to prove that a user or application is genuinely who that person or what that application claims to be.

Authorization in IBM MQ

You can use authorization to limit what particular individuals or applications can do in your IBM MQ environment.

Here are some examples of authorization in an IBM MQ environment:

- Allowing only an authorized administrator to issue commands to manage IBM MQ resources.
- Allowing an application to connect to a queue manager only if the user ID associated with the application is authorized to do so.
- Allowing an application to open only those queues that are necessary for its function.
- Allowing an application to subscribe only to those topics that are necessary for its function.
- Allowing an application to perform only those operations on a queue that are necessary for its function. For example, an application might need only to browse messages on a particular queue, and not to put or get messages.

For more information on how you set up authorization, see "Planning authorization" on page 447 and the associated sub-topics.

Related concepts:

"Authorization" on page 379
Authorization protects critical resources in a system by limiting access only to authorized users and their applications. It prevents the unauthorized use of a resource or the use of a resource in an unauthorized manner.

Auditing in IBM MQ

IBM MQ can issue event messages to record that unusual activity has taken place.

Here are some examples of auditing in an IBM MQ environment:

- An application attempts to open a queue that it is not authorized to open. An instrumentation event message is issued. By inspecting the event message, you discover that this attempt occurred and can decide what action is necessary.
- An application attempts to open a channel, but the attempt fails because SSL does not allow the connection. An instrumentation event message is issued. By inspecting the event message, you discover that this attempt occurred and can decide what action is necessary.

Related concepts:

"Auditing" on page 379
Auditing is the process of recording and checking events to detect whether any unexpected or unauthorized activity has taken place, or whether any attempt has been made to perform such activity.

Confidentiality in IBM MQ

You can implement confidentiality in IBM MQ by encrypting messages.

Confidentiality can be ensured in an IBM MQ environment as follows:

- After a sending MCA gets a message from a transmission queue, IBM MQ uses SSL or TLS to encrypt the message before it is sent over the network to the receiving MCA. At the other end of the channel, the message is decrypted before the receiving MCA puts it on its destination queue.
- While messages are stored on a local queue, the access control mechanisms provided by IBM MQ might be considered sufficient to protect their contents against unauthorized disclosure. However, for a greater level of security, you can use IBM MQ Advanced Message Security to encrypt the messages stored in the queues.

Related concepts:

"Confidentiality" on page 379
The *confidentiality* service protects sensitive information from unauthorized disclosure.

Data integrity in IBM MQ

You can use a data integrity service to detect whether a message has been modified.

Data integrity can be ensured in an IBM MQ environment as follows:

- You can use SSL or TLS to detect whether the contents of a message have been deliberately modified while it was being transmitted over a network. In SSL and TLS, the message digest algorithm provides detection of modified messages in transit.

  All IBM MQ CipherSpecs provide a message digest algorithm, except for TLS_RSA_WITH_NULL_NULL, which does not provide message data integrity.

  IBM MQ detects modified messages upon receiving them; on receiving a modified message, IBM MQ throws an AMQ9661 error message and the channel stops.
- While messages are stored on a local queue, the access control mechanisms provided by IBM MQ might be considered sufficient to prevent deliberate modification of the contents of the messages.

  However, for a greater level of security, you can use IBM MQ Advanced Message Security to detect whether the contents of a message have been deliberately modified between the time the message was put on the queue and the time it was retrieved from the queue.

Upon detecting a modified message, the application attempting to receive the message receives a 2063 return code and, if using an MQGET call, the message is moved to the SYSTEM.PROTECTION.ERROR.QUEUE

Related concepts:

"Data integrity" on page 379
The *data integrity* service detects whether there has been unauthorized modification of data.

Cryptography in IBM MQ

IBM MQ provides cryptography by using the Secure sockets Layer (SSL) and Transport Security Layer (TLS) protocols.

For more information see "SSL and TLS security protocols in IBM MQ."

Related concepts:

"Cryptographic concepts" on page 380
This collection of topics describes the concepts of cryptography applicable to IBM MQ.

SSL and TLS security protocols in IBM MQ

IBM MQ supports both the Transport Layer Security (TLS) and the Secure Sockets Layer (SSL) protocols to provide link level security for message channels and MQI channels.

Message channels and MQI channels can use the SSL or TLS protocol to provide link level security. A caller MCA is an SSL or TLS client and a responder MCA is an SSL or TLS server. IBM MQ supports Version 3.0 of the SSL protocol and Version 1.0 and Version 1.2 of the TLS protocol. You can specify the cryptographic algorithms that are used by the SSL or protocol by supplying a CipherSpec as part of the channel definition.

Note: V 8.0.0.2 From IBM MQ Version 8.0.0, Fix Pack 2, the SSLv3 protocol and the use of some IBM MQ CipherSpecs is deprecated. For more information, see Deprecation: SSLv3 protocol.

You can use the SECPROT parameter to display the security protocol in use on a channel.

At each end of a message channel, and at the server end of an MQI channel, the MCA acts on behalf of the queue manager to which it is connected. During the SSL or TLS handshake, the MCA sends the digital certificate of the queue manager to its partner MCA at the other end of the channel. The IBM MQ code at the client end of an MQI channel acts on behalf of the user of the IBM MQ client application. During the SSL or TLS handshake, the IBM MQ code sends the user's digital certificate to the MCA at the server end of the MQI channel.

Queue managers and IBM MQ client users are not required to have personal digital certificates associated with them when they are acting as SSL or TLS clients, unless SSLCAUTH(REQUIRED) is specified at the server side of the channel.

Digital certificates are stored in a *key repository*. The queue manager attribute **`SSLKeyRepository`** specifies the location of the key repository that holds the queue manager's digital certificate. On an IBM MQ client system, the MQSSLKEYR environment variable specifies the location of the key repository that holds the user's digital certificate. Alternatively, an IBM MQ client application can specify its location in the **`KeyRepository`** field of the SSL and TLS configuration options structure, MQSCO, on an MQCONNX call. See the related topics for more information about key repositories and how to specify where they are located.

Support for SSL and TLS

IBM MQ provides support for SSL Version 3.0 and TLS 1.0 and TLS 1.2 according to the platform you are using. For more information about the SSL and TLS protocols, refer to the information in the subtopics.

IBM i
SSL and TLS support is integral to the IBM i operating system.

Java and JMS clients
These clients use the JVM to provide SSL and TLS support.

HP Integrity NonStop Server, UNIX, Linux, and Windows systems
SSL and TLS support is installed with IBM MQ.

z/OS SSL and TLS support is integral to the z/OS operating system. The SSL and TLS support on z/OS is known as *System SSL*.

For information about any prerequisites for IBM MQ SSL and TLS support, see IBM MQ System Requirements.

Related concepts:

"Cryptographic security protocols: SSL and TLS" on page 388
Cryptographic protocols provide secure connections, enabling two parties to communicate with privacy and data integrity. The Transport Layer Security (TLS) protocol evolved from that of the Secure Sockets Layer (SSL). IBM MQ supports both SSL and TLS.

The SSL or TLS key repository:

A mutually authenticated SSL or TLS connection requires a key repository at each end of the connection. The key repository includes digital certificates and private keys.

This information uses the general term *key repository* to describe the store for digital certificates and their associated private keys. The key repository is referred to by different names on different platforms and environments that support SSL and TLS:

- IBM i On IBM i: *certificate store*
- On Java and JMS: *keystore* and *truststore*
- UNIX Linux Windows On UNIX, Linux, and Windows systems: *key database file*
- z/OS On z/OS: *keyring*

For more information, see "Digital certificates" on page 382 and "Secure Sockets Layer (SSL) and Transport Layer Security (TLS) concepts" on page 388.

A mutually authenticated SSL or TLS connection requires a key repository at each end of the connection. The key repository can contain the following certificates and requests:

- A number of CA certificates from various Certification Authorities that allow the queue manager or client to verify certificates that it receives from its partner at the remote end of the connection. Individual certificates might be in a certificate chain.
- One or more personal certificates received from a Certification Authority. You associate a separate personal certificate with each queue manager or IBM MQ MQI client. Personal certificates are essential on an SSL or TLS client if mutual authentication is required. If mutual authentication is not required, personal certificates are not needed on the client. The key repository might also contain the private key corresponding to each personal certificate.
- Certificate requests which are waiting to be signed by a trusted CA certificate.

For more information about protecting your key repository, see "Protecting IBM MQ key repositories" on page 399.

The location of the key repository depends on the platform you are using:

IBM i **IBM i**
The key repository is a certificate store. The default system certificate store is located at

/QIBM/UserData/ICSS/Cert/Server/Default in the integrated file system (IFS). IBM MQ stores the password for the certificate store in a *password stash file*. For example, the stash file for queue manager QM1 is /QIBM/UserData/mqm/qmgrs/QM1/ssl/Stash.sth.

Alternatively, you can specify that the IBM i system certificate store is to be used instead. To do this change the value of the queue manager **SSLKEYR** attribute to *SYSTEM. This value indicates that the queue manager must use the system certificate store, and the queue manager is registered for use as an application with Digital Certificate Manager (DCM).

The certificate store also contains the private key for the queue manager.

UNIX Linux Windows UNIX, Linux, and Windows systems

The key repository is a key database file. The name of the key database file must have a file extension of .kdb. For example, on UNIX and Linux, the default key database file for queue manager QM1 is /var/mqm/qmgrs/QM1/ssl/key.kdb. If IBM MQ is installed in the default location, the equivalent path on Windows is C:\ProgramData\IBM\MQ\Qmgrs\QM1\ssl\key.kdb.

Each key database file has an associated password stash file. This file holds encoded passwords that allow programs to access the key database. The password stash file must be in the same directory and have the same file stem as the key database, and must end with the suffix .sth, for example /var/mqm/qmgrs/QM1/ssl/key.sth

Note: PKCS #11 cryptographic hardware cards can contain the certificates and keys that are otherwise held in a key database file. When certificates and keys are held on PKCS #11 cards, IBM MQ still requires access to both a key database file and a password stash file.

On UNIX and Windows systems, the key database also contains the private key for the personal certificate associated with the queue manager or IBM MQ MQI client.

z/OS z/OS

Certificates are held in a keyring in z/OS.

Other external security managers (ESMs) also use keyrings for storing certificates.

Private keys are managed by RACF.

Protecting IBM MQ key repositories:

The key repository for IBM MQ is a file. Ensure that only the intended user can access the key repository file. This prevents an intruder or other unauthorized user copying the key repository file to another system, and then setting up an identical user ID on that system to impersonate the intended user.

The permissions on the files depend on the user's umask and which tool is used. On Windows, IBM MQ accounts require permission BypassTraverseChecking which means the permissions of the folders in the file path have no effect.

Check the file permissions of key repository files and make sure that the files and containing folder are not world readable, preferably not even group readable.

Making the keystore read-only is good practice, on whichever system you use, with only the administrator being permitted to enable write operations in order to perform maintenance.

In practice, you must protect all the keystores, whatever the location and whether they are password protected or not; protect the key repositories.

Digital certificate labels, understanding the requirements:

When setting up SSL and TLS to use digital certificates, there might be specific label requirements that you must follow, depending on the platform used and the method you use to connect.

What is the certificate label?

A certificate label is a unique identifier representing a digital certificate stored in a key repository, and provides a convenient human-readable name with which to refer to a particular certificate when performing key management functions. You assign the certificate label when adding a certificate to a key repository for the first time.

The certificate label is separate from the certificate's **`Subject Distinguished Name`** or **`Subject Common Name`** fields. Note that **`Subject Distinguished Name`** and **`Subject Common Name`** are fields within the certificate itself. These are defined when the certificate is created and cannot be changed. If necessary, however, you can change the label associated with a digital certificate.

Certificate label syntax

A certificate label can contain letters, numbers, and punctuation with the following conditions:

- distributed IBM i The certificate label can contain up to 64 characters.
- z/OS The certificate label can contain up to 32 characters.
- The certificate label cannot contain spaces.
- Labels are case sensitive.
- On systems that use EBCDIC katakana, you cannot use lowercase characters.
- IBM MQ client for HP Integrity NonStop Server certificate labels cannot contain forward-slash (/), back-slash (\), tilde (⌂), dollar ($) or more than one consecutive period (.).

Additional requirements for certificate label values are specified in the following sections.

How is the certificate label used?

IBM MQ uses certificate labels to locate a personal certificate that is sent during the SSL handshake. This eliminates ambiguity when more than one personal certificate exists in the key repository.

You can set the certificate label to a value of your choice . If you do not set a value, a default label is used that follows a naming convention depending on the platform that you are using. For details, see the sections that follow, about particular platforms.

Notes:
1. You cannot set the certificate label yourself on Java or JMS systems.
2. Auto-defined channels created by a channel automatic definition (CHAD) exit cannot set the certificate label, because the SSL or TLS handshake has occurred by the time the channel is created. Setting the certificate label in a CHAD exit for inbound channels has no effect.

In this context, an SSL or TLS client refers to the connection partner initiating the handshake, which might be an IBM MQ client or another queue manager.

During the SSL or TLS handshake, the SSL or TLS client always obtains and validates a digital certificate from the server. With the IBM MQ implementation, the SSL or TLS server always requests a certificate from the client and the client always provides a certificate to the server if one is found. If the client is unable to locate a personal certificate, the client sends a `no certificate` response to the server.

The SSL or TLS server always validates the client certificate if one is sent. If the client does not send a certificate, authentication fails if the end of the channel that is acting as the SSL or TLS server is defined with either the **SSLCAUTH** parameter set to *REQUIRED* or an **SSLPEER** parameter value set.

Note that inbound channels (including receiver, cluster-receiver, unqualified server, and server-connection channels) only send the configured certificate if the IBM MQ version of the remote peer fully supports certificate label configuration, and the channel is using a TLS CipherSpec.

In all other cases, the queue manager **CERTLABL** parameter determines the certificate sent. In particular, the following only ever receive the certificate configured by the **CERTLABL** parameter of the queue manager, regardless of the channel-specific label setting:

- All current Java and JMS clients.
- Versions of IBM MQ prior to Version 8.0.

Additionally, the certificate used by a channel must be appropriate for the channel CipherSpec - see "Digital certificates and CipherSpec compatibility in IBM MQ" on page 419 for further information.

IBM MQ Version 8.0 supports the use of multiple certificates on the same queue manager, using a per-channel certificate label attribute. Inbound channels to the queue manager (for example, server connection or receiver) rely on detecting the channel name using TLS Server Name Indication (SNI), in order to present the correct certificate from the queue manager.

If you use MQIPT with a route that has both *SSLServer* and *SSLClient* set, there are two separate TLS sessions between the endpoints, and the SNI data will not flow across the session break.

You can use separate MQIPT routes to get multiple certificate support by selecting the appropriate certificate, for example through the *SSLServerSiteLabel* and *SSLClientSiteLabel* route properties. Alternatively, use MQIPT *SSLProxyMode* which forwards all SSL or TLS control flows intact, including the SNI name.

Note that multiple certificates across MQIPT work only if you are using SSL or TLS proxy mode.

See the SSL/TLS support section of the *IBM MQ Internet Pass-Thru* documentation for more information.

For more information about connecting a queue manager using one-way authentication, that is, when the SSL or TLS client does not send a certificate, see Connecting two queue managers using one-way authentication.

IBM i, UNIX, Linux, and Windows systems

IBM i UNIX Linux Windows The SSL or TLS server sends a certificate to the client.

For queue managers and clients respectively, the following sources are searched in sequence for a non-empty value. The first non-empty value determines the certificate label. The certificate label must exist in the key repository. If no matching certificate in the correct case and format is found that matches a label, an error occurs and the SSL or TLS handshake fails.

Queue managers

1. Channel certificate label attribute **CERTLABL**.
2. Queue manager certificate label attribute **CERTLABL**.
3. A default, which is in the format: `ibmwebspheremq` with the name of the queue manager appended, all in lowercase. For example, for a queue manager named `QM1`, the default certificate label is `ibmwebspheremqqm1`.

IBM MQ clients

1. Channel certificate label attribute, **CERTLABL**.
2. MQSCO structure **CertificateLabel** attribute.
3. Environment variable **MQCERTLABL**.
4. Client `.ini` file (in its SSL section) **CertificateLabel** attribute
5. A default, which is in the format: `ibmwebspheremq` with the user ID that the client application is running as appended, all in lowercase. For example, for a user ID of `USER1`, the default certificate label is `ibmwebspheremquser1`.

z/OS

z/OS

z/OS IBM MQ Clients are not supported on z/OS systems. However, a z/OS queue manager can act in the role of an SSL or TLS client when initiating a connection, or an SSL or TLS server when accepting a connection request. Certificate label requirements for z/OS queue managers apply in both of these roles, and differ from the requirements on distributed platforms.

For queue managers and clients respectively, the following sources are searched in sequence for a non-empty value. The first non-empty value determines the certificate label. The certificate label must exist in the key repository. If no matching certificate in the correct case and format is found that matches a label, an error occurs and the SSL or TLS handshake fails.

1. Channel certificate label attribute, **CERTLABL**.
2. If shared, the queue-sharing group certificate label attribute, **CERTQSGL**.

   If not shared, the queue manager certificate label attribute, **CERTLABL**.
3. A default, which is in the format: `ibmWebSphereMQ` with the name of the queue manager or queue sharing group appended. Note that this string is case-sensitive and must be written as shown. For example, for a queue manager named `QM1`, the default certificate label is `ibmWebSphereMQQM1`.

For information on how to display the key repository, see "Locating the key repository for a queue manager on z/OS" on page 705.

IBM MQ Java and IBM MQ JMS clients

IBM MQ Java and IBM MQ JMS clients use the facilities of their Java Secure Socket Extension (JSSE) provider to select a personal certificate during the SSL or TLS handshake and are not therefore subject to certificate label requirements.

The default behavior is that the JSSE client iterates through the certificates in the key repository, selecting the first acceptable personal certificate found. However, this behavior is only a default, and is dependent on the implementation of the JSSE provider.

In addition, the JSSE interface is highly customizable through configuration and direct access at runtime by the application. Consult the documentation supplied by your JSSE provider for specific details.

For troubleshooting, or to better understand the handshake performed by the IBM MQ Java client application in combination with your specific JSSE provider, you can enable debugging by setting `javax.net.debug=ssl` in the JVM environment.

You can set the variable within the application, through configuration, or by entering `-Djavax.net.debug=ssl` on the command line.

IBM MQ client for HP Integrity NonStop Server

IBM MQ client for HP Integrity NonStop Server uses the channel **CERTLABL** attribute (or the value of the **MQCERTLABL** environment variable) to choose a certificate to be used for an SSL connection.

The certificate label, whether derived from the channel's **CERTLABL** attribute or from the value of the **MQCERTLABL** environment variable, is used to construct the name of the cert*.pem file and the corresponding Stash*.sth file.

```
cert_<CERTLABL>.pem
Stash_<CERTLABL>.sth
```

If the channel does not have a **CERTLABL** attribute and the **MQCERTLABL** environment variable is not present, then IBM MQ uses the following certificate and stash files:

```
cert_default_ <userid>.pem
Stash_default_ <userid>.sth
```

where <*userid* > is the name of the user that is executing the IBM MQ client program.

If the cert_default_<userid>.pem file or the Stash_default_<userid>.sth file does not exist, then IBM MQ uses the following certificate and stash files:

```
cert.pem
Stash.sth
```

Note:

1. The fallback to the cert_default_<userid>.pem and Stash_default_<userid>.sth files or the unqualified cert.pem and Stash.sth files only occurs if a certificate label is available from neither the channel's **CERTLABL** attribute nor the **MQCERTLABL** environment variable. If a **CERTLABL** is specified, then the associated cert_< *label* >.pem and Stash_ <*label*>.sth files must exist and be accessible for the connection to proceed.
2. IBM MQ rejects certificate labels containing any of the following characters:

   /

   \

   ⌂

   $

   and also rejects certificate labels containing more than one consecutive dot (.)

Refreshing the queue manager's key repository:

When you change the contents of a key repository, the queue manager does not immediately pick up the new contents. For a queue manager to use the new key repository contents, you must issue the REFRESH SECURITY TYPE(SSL) command.

This process is intentional, and prevents the situation where multiple running channels could use different versions of a key repository. As a security control, only one version of a key repository can be loaded by the queue manager at any time.

For more information about the REFRESH SECURITY TYPE(SSL) command, see REFRESH SECURITY.

You can also refresh a key repository using PCF commands or the IBM MQ Explorer. For more information, see the MQCMD_REFRESH_SECURITY command and the topic *Refreshing SSL or TLS Security* in the IBM MQ Explorer section of this product documentation.

Related concepts:
"Refreshing a client's view of the SSL key repository contents and SSL settings"
To update the client application with the refreshed contents of the key repository, you must stop and restart the client application.

Refreshing a client's view of the SSL key repository contents and SSL settings:

To update the client application with the refreshed contents of the key repository, you must stop and restart the client application.

You cannot refresh security on an IBM MQ client; there is no equivalent of the REFRESH SECURITY TYPE(SSL) command for clients (see REFRESH SECURITY) for more information.

You must stop and restart the application, whenever you change the security certificate, to update the client application with the refreshed contents of the key repository.

If restarting the channel refreshes the configurations, and if your application has reconnection logic, it is possible for you to refresh security at the client by issuing the STOP CHL STATUS(INACTIVE) command.
Related concepts:
"Refreshing the queue manager's key repository" on page 403
When you change the contents of a key repository, the queue manager does not immediately pick up the new contents. For a queue manager to use the new key repository contents, you must issue the REFRESH SECURITY TYPE(SSL) command.

MQCSP password protection:

From IBM MQ Version 8.0 , you can send passwords that are included in the MQCSP structure either protected, by using IBM MQ functionality, or encrypted, by using SSL/TLS encryption.

MQCSP password protection is useful for test and development purposes as using MQCSP password protection is simpler than setting up TLS encryption, but not as secure. For production purposes, you should use TLS encryption in preference to IBM MQ password protection, especially when the network between the client and queue manager is untrusted, as TLS encryption is more secure.

If you are concerned precisely what encryption is being used, and how much protection it offers, you need to use full TLS encryption. In this situation, the algorithms are publicly known, and you can select the appropriate one for your enterprise by using the **SSLCIPH** channel attribute.

For more information about the MQCSP structure, see MQCSP structure.

Password protection is used when all of the following conditions are met:
- Both ends of the connection are using IBM MQ Version 8.0, or later.
- The channel is not using TLS encryption. A channel is not using TLS encryption if the channel has a blank **SSLCIPH** attribute, or the **SSLCIPH** attribute is set to a CipherSpec that does not provide encryption. Null ciphers, for example, NULL_SHA, do not provide encryption.
- You set **MQCSP**.**AuthenticationType** to MQCSP_AUTH_USER_ID_AND_PWD. Setting this value enables more checks to be evaluated to decide whether password protection is done. The default value of **MQCSP**.**AuthenticationType** is MQCSP_AUTH_NONE. With the default setting, no password protection is done. For more information, see **AuthenticationType**.
- If the client is IBM MQ Explorer and user identification compatibility mode is not enabled, which is not the default. This condition is applicable only to IBM MQ Explorer.

If these conditions are not met, the password is sent in plain text unless prohibited by the **PasswordProtection** configuration setting.

The `PasswordProtection` configuration setting

The **`PasswordProtection`** attribute in the Channels section of the client and queue manager .ini configuration files can prevent passwords from being sent in plain text. The attribute can take 1 of 3 values. The default value is `compatible`:

compatible

The password can be sent in plain text if either the queue manager or client is running a version of IBM MQ earlier than Version 8.0. That is, plain text passwords are allowed for compatibility.

Therefore:

- The password is sent encrypted by the TLS CipherSpec if TLS encryption is used and the CipherSpec is not null.
- The password is sent in plain text if either the queue manager or the client is running a version of IBM MQ earlier than Version 8.0, and TLS encryption is not used. The password is sent in plain text as versions of IBM MQ earlier than Version 8.0 can send passwords only in plain text.
- The password is sent protected if both the queue manager and the client are running a version of IBM MQ at Version 8.0 or later, and either a null CipherSpec is used, or TLS encryption is not used. **`MQCSP`**.**`AuthenticationType`** must be set to MQCSP_AUTH_USER_ID_AND_PWD.
- The connection fails before the password is sent if both the queue manager and the client are running a version of IBM MQ at Version 8.0 or later, and **`MQCSP`**.**`AuthenticationType`** is not set to MQCSP_AUTH_USER_ID_AND_PWD.

always

The password must be either encrypted with a CipherSpec that is not a null CipherSpec, or **`MQCSP`**.**`AuthenticationType`** must be set to MQCSP_AUTH_USER_ID_AND_PWD. Otherwise, the connection fails. That is, plain text passwords are not allowed.

Therefore:

- The password is sent encrypted by the TLS CipherSpec if TLS encryption is used and the CipherSpec is not null.
- The password is sent protected if both the queue manager and the client are running a version of IBM MQ at Version 8.0 or later, and either TLS encryption is not used, or a null CipherSpec is used. **`MQCSP`**.**`AuthenticationType`** must be set to MQCSP_AUTH_USER_ID_AND_PWD.
- The connection fails before the password is sent if either the queue manager or the client is running a version of IBM MQ earlier than Version 8.0, and TLS encryption is not used. As versions of IBM MQ earlier than Version 8.0 can send passwords only in plain text, and `always` requires the password to be either encrypted or protected, the connection fails.

optional

The password can optionally be sent protected, but is sent in plain text if **`MQCSP`**.**`AuthenticationType`** is not set to MQCSP_AUTH_USER_ID_AND_PWD. That is, plain text passwords are allowed to be sent by any client.

Therefore:

- The password is sent encrypted by the TLS CipherSpec if TLS encryption is used and the CipherSpec is not null.
- The password is sent in plain text if a null CipherSpec is used and **`MQCSP`**.**`AuthenticationType`** is not set to MQCSP_AUTH_USER_ID_AND_PWD.
- The password is sent in plain text if either the queue manager or the client is running a version of IBM MQ earlier than Version 8.0, and TLS encryption is not used. The password is sent in plain text as versions of IBM MQ earlier than Version 8.0 can send passwords only in plain text.

- The password is sent protected if both the queue manager and the client are running a version of IBM MQ at Version 8.0 or later, TLS encryption is not used or a null CipherSpec is used, and **MQCSP**.**AuthenticationType** is set to MQCSP_AUTH_USER_ID_AND_PWD.

For Java and JMS clients, the behavior of the **PasswordProtection** attribute changes dependent on the choice of using compatibility mode or MQCSP mode:

- If Java and JMS clients are operating in compatibility mode, an MQCSP structure is not flowed during connection processing. Therefore, the behavior of the **PasswordProtection** attribute is the same behavior as described for clients that are running a version of IBM MQ earlier than Version 8.0.
- If Java and JMS clients are operating in MQCSP mode, the behavior of the **PasswordProtection** attribute is the behavior as described.

For more information about connection authentication with Java and JMS clients, see "Connection authentication with the Java client" on page 442.

Digital Certificate Manager (DCM):

Use the DCM to manage digital certificates and private keys on IBM i.

The Digital Certificate Manager (DCM) enables you to manage digital certificates and to use them in secure applications on the IBM i server. With Digital Certificate Manager, you can request and process digital certificates from Certificate Authorities (CAs) or other third-parties. You can also act as a local Certificate Authority to create and manage digital certificates for your users.

DCM also supports using Certificate Revocation Lists (CRLs) to provide a stronger certificate and application validation process. You can use DCM to define the location where a specific Certificate Authority CRL resides on an LDAP server so that IBM MQ can verify that a specific certificate has not been revoked.

DCM supports and can automatically detect certificates in a variety of formats. When DCM detects a PKCS #12 encoded certificate, or a PKCS #7 certificate that contains encrypted data, it automatically prompts the user to enter the password that was used to encrypt the certificate. DCM does not prompt for PKCS #7 certificates that do not contain encrypted data.

DCM provides a browser-based user interface that you can use to manage digital certificates for your applications and users. The user interface is divided into two main frames: a navigation frame and a task frame.

You use the navigation frame to select the tasks to manage certificates or the applications that use them. Some individual tasks are shown directly in the main navigation frame, but most tasks in the navigation frame are organized into categories. For example, Manage Certificates is a task category that contains various individual guided tasks, such as View certificate, Renew certificate, and Import certificate. If an item in the navigation frame is a category that contains more than one task, an arrow is displayed to the left of it. The arrow indicates that when you select the category link, an expanded list of tasks displays, enabling you to choose which task to perform.

For important information about DCM, see the following IBM Redbooks® publications:

- *IBM i Wired Network Security: OS/400 V5R1 DCM and Cryptographic Enhancements*, SG24-6168. Specifically, see the appendixes for essential information about setting up your IBM i system as a local CA.
- *AS/400 Internet Security: Developing a Digital Certificate Infrastructure*, SG24-5659. Specifically, see Chapter 5. *Digital Certificate Manager for AS/400* , which explains the AS/400 DCM.

Federal Information Processing Standards (FIPS):

This topic introduces the Federal Information Processing Standards (FIPS) Cryptomodule Validation Program of the US National Institute of Standards and Technology and the cryptographic functions which can be used on SSL or TLS channels.

This information applies to the following platforms:
- Windows
- UNIX and Linux
- z/OS

The FIPS 140-2 compliance of an IBM MQ SSL or TLS connection on UNIX, Linux, and Windows systems is found here "Federal Information Processing Standards (FIPS) for UNIX, Linux, and Windows."

z/OS The FIPS 140-2 compliance of an IBM MQ SSL or TLS connection on z/OS is found here "Federal Information Processing Standards (FIPS) for z/OS" on page 410.

If cryptographic hardware is present, the cryptographic modules used by IBM MQ can be configured to be those provided by the hardware manufacturer. If this is done, the configuration is only FIPS-compliant if those cryptographic modules are FIPS-certified.

Over time, the Federal Information Processing Standards are updated to reflect new attacks against encryption algorithms and protocols. For example, some CipherSpecs may cease to be FIPS certified. When such changes occur, IBM MQ is also updated to implement the latest standard. As a result, you might see changes in behavior after applying maintenance.

The IBM MQ product readme lists the version of FIPS enforced by each product maintenance level. If you configure IBM MQ to enforce FIPS compliance, always consult the readme when planning to apply maintenance. The readme is located at IBM MQ product READMEs

Using Secure Sockets Layer (SSL) with IBM MQ classes for JMS

"Federal Information Processing Standards" on page 394
The US government produces technical advice on IT systems and security, including data encryption. The National Institute for Standards and Technology (NIST) is an important body concerned with IT systems and security. NIST produces recommendations and standards, including the Federal Information Processing Standards (FIPS).

Federal Information Processing Standards (FIPS) for UNIX, Linux, and Windows:

When cryptography is required on an SSL or TLS channel on Windows, UNIX and Linux systems, IBM MQ uses a cryptography package called IBM Crypto for C (ICC). On the Windows, UNIX and Linux platforms, the ICC software has passed the Federal Information Processing Standards (FIPS) Cryptomodule Validation Program of the US National Institute of Standards and Technology, at level 140-2.

The FIPS 140-2 compliance of an IBM MQ SSL or TLS connection on Windows, UNIX and Linux systems is as follows:

- For all IBM MQ message channels (except CLNTCONN channel types), the connection is FIPS-compliant if the following conditions are met:
  - The installed GSKit ICC version has been certified FIPS 140-2 compliant on the installed operating system version and hardware architecture.
  - The queue manager's SSLFIPS attribute has been set to YES.
  - All key repositories have been created and manipulated using only FIPS-compliant software, such as **runmqakm** with the `-fips` option.
- For all IBM MQ MQI client applications , the connection uses GSKit and is FIPS-compliant if the following conditions are met:
  - The installed GSKit ICC version has been certified FIPS 140-2 compliant on the installed operating system version and hardware architecture.
  - You have specified that only FIPS-certified cryptography is to be used, as described in the related topic for the MQI client.
  - All key repositories have been created and manipulated using only FIPS-compliant software, such as **runmqakm** with the `-fips` option.
- For IBM MQ classes for Java applications using client mode, the connection uses the JRE's SSL and TLS implementations and is FIPS-compliant if the following conditions are met:
  - The Java Runtime Environment used to run the application is FIPS-compliant on the installed operating system version and hardware architecture.
  - You have specified that only FIPS-certified cryptography is to be used, as described in the related topic for the Java client.
  - All key repositories have been created and manipulated using only FIPS-compliant software, such as **runmqakm** with the `-fips` option.
- For IBM MQ classes for JMS applications using client mode, the connection uses the JRE's SSL and TLS implementations and is FIPS-compliant if the following conditions are met:
  - The Java Runtime Environment used to run the application is FIPS-compliant on the installed operating system version and hardware architecture.
  - You have specified that only FIPS-certified cryptography is to be used, as described in the related topic for the JMS client.
  - All key repositories have been created and manipulated using only FIPS-compliant software, such as **runmqakm** with the `-fips` option.
- For unmanaged .NET client applications, the connection uses GSKit and is FIPS-compliant if the following conditions are met:
  - The installed GSKit ICC version has been certified FIPS 140-2 compliant on the installed operating system version and hardware architecture.
  - You have specified that only FIPS-certified cryptography is to be used, as described in the related topic for the .NET client.
  - All key repositories have been created and manipulated using only FIPS-compliant software, such as **runmqakm** with the `-fips` option.
- For unmanaged XMS .NET client applications, the connection uses GSKit and is FIPS-compliant if the following conditions are met:
  - The installed GSKit ICC version has been certified FIPS 140-2 compliant on the installed operating system version and hardware architecture.
  - You have specified that only FIPS-certified cryptography is to be used, as described in the XMS .NET documentation.
  - All key repositories have been created and manipulated using only FIPS-compliant software, such as **runmqakm** with the `-fips` option.

All supported platforms are FIPS 140-2 certified except as noted in the readme file included with each fix pack or refresh pack.

For SSL and TLS connections using GSKit, the component which is FIPS 140-2 certified is named *ICC*. It is the version of this component which determines GSKit FIPS compliance on any given platform. To determine the ICC version currently installed, run the **dspmqver -p 64 -v** command.

Here is an example extract of the **dspmqver -p 64 -v** output relating to ICC:

```
ICC

The NIST certification statement for GSKit ICC 8 (included in GSKit 8) can be found at the following address: http://csrc.nist.gov/groups/STM/cmvp/documents/140-1/1401val2013.htm#1994.

If cryptographic hardware is present, the cryptographic modules used by IBM MQ can be configured to be those provided by the hardware manufacturer. If this is done, the configuration is only FIPS-compliant if those cryptographic modules are FIPS-certified.

Note: 32 bit Solaris x86 SSL and TLS clients configured for FIPS 140-2 compliant operation fail when running on Intel systems. This failure occurs because the FIPS 140-2 compliant GSKit-Crypto Solaris x86 32 bit library file does not load on the Intel chipset. On affected systems, error AMQ9655 is reported in the client error log. To resolve this issue, disable FIPS 140-2 compliance or recompile the client application 64 bit, because 64 bit code is not affected.

Triple DES restrictions enforced when operating in compliance with FIPS 140-2

When IBM MQ is configured to operate in compliance with FIPS 140-2, additional restrictions are enforced in relation to Triple DES (3DES) CipherSpecs. These restrictions enable compliance with the US NIST SP800-67 recommendation.

1. All parts of the Triple DES key must be unique.
2. No part of the Triple DES key can be a Weak, Semi-Weak, or Possibly-Weak key according to the definitions in NIST SP800-67.
3. No more than 32 GB of data can be transmitted over the connection before a secret key reset must occur. By default, IBM MQ does not reset the secret session key so this reset must be configured. Failure to enable secret key reset when using a Triple DES CipherSpec and FIPS 140-2 compliance results in the connection closing with error AMQ9288 after the maximum byte count is exceeded. For information about how to configure secret key reset, see "Resetting SSL and TLS secret keys" on page 804.

IBM MQ generates Triple DES session keys which already comply with rules 1 and 2. However, to satisfy the third restriction you must enable secret key reset when using Triple DES CipherSpecs in a FIPS 140-2 configuration. Alternatively, you can avoid using Triple DES.

"Federal Information Processing Standards" on page 394
The US government produces technical advice on IT systems and security, including data encryption. The National Institute for Standards and Technology (NIST) is an important body concerned with IT systems and security. NIST produces recommendations and standards, including the Federal Information Processing Standards (FIPS).

Federal Information Processing Standards (FIPS) for z/OS:

When cryptography is required on an SSL or TLS channel on z/OS , IBM MQ uses a service called System SSL. The objective of System SSL is to provide the capability to execute securely in a mode designed to adhere to the Federal Information Processing Standards (FIPS) Cryptomodule Validation Program of the US National Institute of Standards and Technology, at level 140-2.

When implementing FIPS 140-2 compliant connections with IBM MQ SSL or TLS connections there are a number of points to consider:

- To enable IBM MQ message channels for FIPS-compliance, ensure the following conditions are met:
  - System SSL Security Level 3 FMID is installed and configured (see Planning to install IBM MQ).
  - System SSL modules are validated.
  - The queue manager's SSLFIPS attribute has been set to **YES**.

When executing in FIPS mode, System SSL exploits CP Assist for Cryptographic Function (CPACF) when available. Cryptographic functions performed by ICSF-supported hardware when running in non-FIPS mode continue to be exploited when executing in FIPS mode, with the exception of RSA signature generation which must be performed in software.

Table 16. Differences between FIPS mode and non-FIPS mode algorithm support.

	Non-FIPS		**FIPS**	
Algorithm	**Key sizes**	**Hardware**	**Key sizes**	**Hardware**
RC2	40 and 128			
RC4	40 and 128			
DES	56	x		
TDES	168	x	168	x
AES	128 and 256	x	128 and 256	x
MD5	48			
SHA-1	160	x	160	x
SHA-2	224, 256, 384 and 512	x	224, 256, 384 and 512	x
RSA	512-4096	x	1024-4096	x
DSA	512-1024		1024	

Table 16. Differences between FIPS mode and non-FIPS mode algorithm support. (continued)

	Non-FIPS		FIPS	
Algorithm	**Key sizes**	**Hardware**	**Key sizes**	**Hardware**
DH	512-2048		2048	

In FIPS mode, System SSL can only use certificates that use the algorithms and key sizes shown in Table 1. During X.509 certificate validation if an algorithm that is incompatible with FIPS mode is encountered, then the certificate cannot be used and is treated as not valid.

For IBM MQ classes applications using client mode within WebSphere Application Server , refer to the Federal Information Processing Standards-approved section of the IBM WebSphere Application Server Version 7 product documentation.

For information on System SSL module configuration, see System SSL Module Verification Setup.

Related information:

"Federal Information Processing Standards" on page 394

SSL and TLS on the IBM MQ MQI client:

IBM MQ supports SSL and TLS on clients. You can tailor the use of SSL or TLS in various ways.

IBM MQ provides SSL and TLS support for IBM MQ MQI clients on Windows, UNIX and Linux systems. If you are using IBM MQ classes for Java, see Using IBM MQ classes for Java and if you are using IBM MQ classes for JMS, see Using IBM MQ classes for JMS. The rest of this section does not apply to the Java or JMS environments.

You can specify the key repository for an IBM MQ MQI client either with the MQSSLKEYR value in your IBM MQ client configuration file, or when your application makes an MQCONNX call. You have three options for specifying that a channel uses SSL:

- Using a channel definition table
- Using the SSL configuration options structure, MQSCO, on an MQCONNX call
- Using the Active Directory (on Windows systems)

You cannot use the MQSERVER environment variable to specify that a channel uses SSL.

You can continue to run your existing IBM MQ MQI client applications without SSL, as long as SSL is not specified at the other end of the channel.

If changes are made on a client machine to the contents of the SSL Key Repository, the location of the SSL Key Repository, the Authentication Information, or the Cryptographic hardware parameters, you need to end all the SSL connections in order to reflect these changes in the client-connection channels that the application is using to connect to the queue manager. Once all the connections have ended, restart the SSL channels. All the new SSL settings are used. These settings are analogous to those refreshed by the REFRESH SECURITY TYPE(SSL) command on queue manager systems.

When your IBM MQ MQI client runs on a Windows, UNIX and Linux system with cryptographic hardware, you configure that hardware with the MQSSLCRYP environment variable. This variable is equivalent to the SSLCRYP parameter on the ALTER QMGR MQSC command. Refer to ALTER QMGR for a description of the SSLCRYP parameter on the ALTER QMGR MQSC command. If you use the GSK_PCS11 version of the SSLCRYP parameter, the PKCS #11 token label must be specified entirely in lower-case.

SSL secret key reset and FIPS are supported on IBM MQ MQI clients. For more information, see "Resetting SSL and TLS secret keys" on page 804 and "Federal Information Processing Standards (FIPS) for UNIX, Linux, and Windows" on page 407.

See "Setting up IBM MQ MQI client security" on page 652 for more information about the SSL support for IBM MQ MQI clients.

Related information:

Configuring a client using a configuration file

Specifying that an MQI channel uses SSL:

For an MQI channel to use SSL, the value of the *SSLCipherSpec* attribute of the client-connection channel must be the name of a CipherSpec that is supported by IBM MQ on the client platform.

You can define a client-connection channel with a value for this attribute in the following ways. They are listed in order of decreasing precedence.

1. When a PreConnect exit provides a channel definition structure to use.

   A PreConnect exit can provide the name of a CipherSpec in the *SSLCipherSpec* field of a channel definition structure, MQCD. This structure is returned in the **ppMQCDArrayPtr** field of the MQNXP exit parameter structure used by the PreConnect exit.
2. When an IBM MQ MQI client application issues an MQCONNX call.

   The application can specify the name of a CipherSpec in the *SSLCipherSpec* field of a channel definition structure, MQCD. This structure is referenced by the connect options structure, MQCNO, which is a parameter on the MQCONNX call.
3. Using a client channel definition table (CCDT).

   One or more entries in a client channel definition table can specify the name of a CipherSpec. For example, if you create an entry by using the DEFINE CHANNEL MQSC command, you can use the SSLCIPH parameter on the command to specify the name of a CipherSpec.
4. Using Active Directory on Windows.

   On Windows systems, you can use the **setmqscp** control command to publish the client-connection channel definitions in Active Directory. One or more of these definitions can specify the name of a CipherSpec.

For example, if a client application provides a client-connection channel definition in an MQCD structure on an MQCONNX call, this definition is used in preference to any entries in a client channel definition table that can be accessed by the IBM MQ client.

You cannot use the MQSERVER environment variable to provide the channel definition at the client end of an MQI channel that uses SSL.

To check whether a client certificate has flowed, display the channel status at the server end of a channel for the presence of a peer name parameter value.

Related concepts:

"Specifying a CipherSpec for an IBM MQ MQI client" on page 803
You have three options for specifying a CipherSpec for an IBM MQ MQI client.

CipherSpecs and CipherSuites in IBM MQ:

From IBM MQ Version 8.0.0, Fix Pack 2 SSL CipherSpecs are deprecated. TLS CipherSpecs are supported, and RSA and Diffie-Hellman algorithms.

IBM MQ supports TLS V1.0 and V1.2 CipherSpecs.

From IBM MQ Version 8.0.0, Fix Pack 2 the SSLv3 protocol and the use of some IBM MQ CipherSpecs is deprecated. For more information, see Deprecation: SSLv3 protocol.

IBM MQ supports the RSA and Diffie-Hellman key exchange and authentication algorithms. The size of the key used during the TSL, or SSL handshake can depend on the digital certificate you use, but some CipherSpecs include a specification of the handshake key size. Larger handshake key sizes provide stronger authentication. With smaller key sizes, the handshake is faster.

Related concepts:

"CipherSpecs and CipherSuites" on page 392
Cryptographic security protocols must agree on the algorithms used by a secure connection. CipherSpecs and CipherSuites define specific combinations of algorithms.

CipherSpec values supported in IBM MQ:

The set of default CipherSpecs allows only the following values:

TLS 1.0

- TLS_RSA_WITH_AES_128_CBC_SHA
- TLS_RSA_WITH_AES_256_CBC_SHA

TLS 1.2

- ECDHE_ECDSA_AES_128_CBC_SHA256
- ECDHE_ECDSA_AES_256_CBC_SHA384
- ECDHE_ECDSA_AES_128_GCM_SHA256
- ECDHE_ECDSA_AES_256_GCM_SHA384
- ECDHE_ECDSA_3DES_EDE_CBC_SHA256
- ECDHE_RSA_AES_128_CBC_SHA256
- ECDHE_RSA_AES_256_CBC_SHA384
- ECDHE_RSA_AES_128_GCM_SHA256
- ECDHE_RSA_AES_256_GCM_SHA384
- TLS_RSA_WITH_AES_128_CBC_SHA256
- TLS_RSA_WITH_AES_256_CBC_SHA256
- TLS_RSA_WITH_AES_128_GCM_SHA256
- TLS_RSA_WITH_AES_256_GCM_SHA384

IBM i The default set of CipherSpecs for IBM MQ for IBM i Version 7.2 and Version 7.3 allows only the following values:

- *TLS_RSA_WITH_AES_128_GCM_SHA256
- *TLS_RSA_WITH_AES_256_GCM_SHA384
- *ECDHE_ECDSA_RC4_128_SHA256

- *ECDHE_ECDSA_3DES_EDE_CBC_SHA256
- *ECDHE_RSA_RC4_128_SHA256
- *ECDHE_RSA_3DES_EDE_CBC_SHA256
- *ECDHE_ECDSA_AES_128_CBC_SHA256
- *ECDHE_ECDSA_AES_256_CBC_SHA384
- *ECDHE_RSA_AES_128_CBC_SHA256
- *ECDHE_RSA_AES_256_CBC_SHA384
- *ECDHE_ECDSA_AES_128_GCM_SHA256
- *ECDHE_ECDSA_AES_256_GCM_SHA384
- *ECDHE_RSA_AES_128_GCM_SHA256
- *ECDHE_RSA_AES_256_GCM_SHA384
- *ECDHE_RSA_NULL_SHA256
- *ECDHE_ECDSA_NULL_SHA256

Enabling deprecated TLS CipherSpecs

By default, you are not allowed to specify a deprecated CipherSpec on a channel definition. If you attempt to specify a deprecated CipherSpec, you receive message AMQ8242: SSLCIPH definition wrong, and PCF returns MQRCCF_SSL_CIPHER_SPEC_ERROR.

You cannot start a channel with a deprecated CipherSpec. If you attempt to do so with a deprecated CipherSpec, the system returns *MQCC_FAILED (2)*, together with a **Reason** of *MQRC_SSL_INITIALIZATION_ERROR (2393)* to the client.

It is possible for you to re-enable one or more of the deprecated CipherSpecs for defining channels, at runtime on the server, by setting the environment variable *AMQ_SSL_WEAK_CIPHER_ENABLE*.

The *AMQ_SSL_WEAK_CIPHER_ENABLE* environment variable accepts:
- A single CipherSpec name, or
- A comma separated list of IBM MQ CipherSpec names to re-enable, or
- The special value of *ALL*, representing all CipherSpecs.

For example, if you want to re-enable ECDHE_RSA_RC4_128_SHA256, set the following environment variable:

```
AMQ_SSL_WEAK_CIPHER_ENABLE=ECDHE_RA_RC4_128_SHA256
```

or, alternatively change the SSL stanza in the `qm.ini` file, by setting:

```
SSL
AllowWeakCipherSpec=ECDHE_RA_RC4_128_SHA256
```

Enabling deprecated SSL CipherSpecs

In addition to issuing `AMQ_SSL_WEAK_CIPHER_ENABLE`, or `AllowWeakCipherSpec`, as described in "Enabling deprecated TLS CipherSpecs," you must set the environment variable `AMQ_SSL_V3_ENABLE=1` or issue `AllowSSLV3=Y` as described in Deprecation:SSLV3 protocol.

For example, if you want to re-enable RC4_MD5_US, set the following environment variables:

```
AMQ_SSL_V3_ENABLE=1
AMQ_SSL_WEAK_CIPHER_ENABLE=RC4_MD5_US
```

or, alternatively, change the SSL stanza in the `qm.ini` file, by setting:

```
SSL
AllowSSLV3=Y
AllowWeakCipherSpec=RC4_MD5_US
```

Related concepts:

"CipherSpecs and CipherSuites" on page 392
Cryptographic security protocols must agree on the algorithms used by a secure connection. CipherSpecs and CipherSuites define specific combinations of algorithms.

NSA Suite B Cryptography in IBM MQ:

This topic provides information about how to configure IBM MQ on Windows, Linux, and UNIX systems to conform to the Suite B compliant TLS 1.2 profile.

Over time, the NSA Cryptography Suite B Standard is updated to reflect new attacks against encryption algorithms and protocols. For example, some CipherSpecs might cease to be Suite B certified. When such changes occur, IBM MQ is also updated to implement the latest standard. As a result, you might see changes in behavior after applying maintenance. The IBM MQ 7.5 readme file lists the version of Suite B enforced by each product maintenance level. If you configure IBM MQ to enforce Suite B compliance, always consult the readme file when planning to apply maintenance. The readme file is at IBM MQ product READMEs.

On Windows, UNIX, and Linux systems, IBM MQ can be configured to conform to the Suite B compliant TLS 1.2 profile at the security levels shown in Table 1.

Table 17. Suite B security levels with allowed CipherSpecs and digital signature algorithms

Security level	Allowed CipherSpecs	Allowed digital signature algorithms
128-bit	ECDHE_ECDSA_AES_128_GCM_SHA256 ECDHE_ECDSA_AES_256_GCM_SHA384	ECDSA with SHA-256 ECDSA with SHA-384
192-bit	ECDHE_ECDSA_AES_256_GCM_SHA384	ECDSA with SHA-384
Both [1]	ECDHE_ECDSA_AES_128_GCM_SHA256 ECDHE_ECDSA_AES_256_GCM_SHA384	ECDSA with SHA-256 ECDSA with SHA-384

1. It is possible to configure both the 128-bit and 192-bit security levels concurrently. Since the Suite B configuration determines the minimum acceptable cryptographic algorithms, configuring both security levels is equivalent to configuring only the 128-bit security level. The cryptographic algorithms of the 192-bit security level are stronger than the minimum required for the 128-bit security level, so they are permitted for the 128-bit security level even if the 192-bit security level is not enabled.

Note: The naming conventions used for the Security level do not necessarily represent the elliptic curve size or the key size of the AES encryption algorithm.

CipherSpec conformation to Suite B

Although the default behavior of IBM MQ is not to comply with the Suite B standard, IBM MQ can be configured to conform to either, or both security levels on Windows, UNIX and Linux systems. Following the successful configuration of IBM MQ to use Suite B, any attempt to start an outbound channel using a CipherSpec not conforming to Suite B results in the error `AMQ9282`. This activity also results in the MQI client returning the reason code `MQRC_CIPHER_SPEC_NOT_SUITE_B`. Similarly, attempting to start an inbound channel using a CipherSpec not conforming to the Suite B configuration results in the error `AMQ9616`.

For more information about IBM MQ CipherSpecs, see "Enabling CipherSpecs" on page 797

Suite B and digital certificates

Suite B restricts the digital signature algorithms which can be used to sign digital certificates. Suite B also restricts the type of public key which certificates can contain. Therefore IBM MQ must be configured to use certificates whose digital signature algorithm and public key type are allowed by the configured Suite B security level of the remote partner. Digital certificates which do not comply with the security level requirements are rejected and the connection fails with error `AMQ9633` or `AMQ9285`.

For the 128-bit Suite B security level, the public key of the certificate subject is required to use either the NIST P-256 elliptic curve or the NIST P-384 elliptic curve and to be signed with either the NIST P-256 elliptic curve or the NIST P-384 elliptic curve. At the 192-bit Suite B security level, the public key of the certificate subject is required to use the NIST P-384 elliptic curve and to be signed with the NIST P-384 elliptic curve.

To obtain a certificate suitable for Suite B compliant operation, use the **`runmqakm`** command and specify the **`-sig_alg`** parameter to request a suitable digital signature algorithm. The `EC_ecdsa_with_SHA256` and `EC_ecdsa_with_SHA384` **`-sig_alg`** parameter values correspond to elliptic curve keys signed by the allowed Suite B digital signature algorithms.

For more information about the **`runmqakm`** command, see runmqckm and runmqakm options.

Note: The **`iKeycmd`** and **`iKeyman`** tools do not support the creation of digital certificates for Suite B compliant operation.

Creating and requesting digital certificates

To create a self-signed digital certificate for Suite B testing, see “Creating a self-signed personal certificate on UNIX, Linux, and Windows systems” on page 681

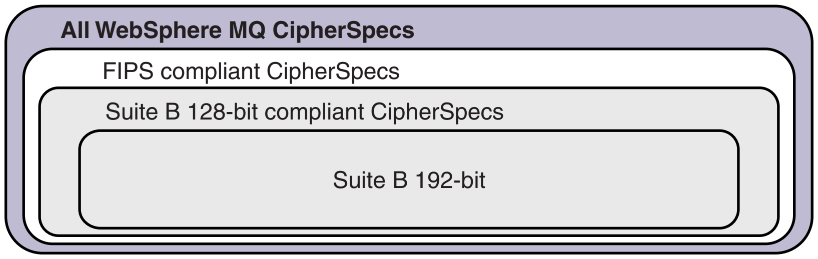
To request a CA-signed digital certificate for Suite B production use, see “Requesting a personal certificate on UNIX, Linux, and Windows systems” on page 683.

Note: The certificate authority being used must generate digital certificates which satisfy the requirements described in IETF RFC 6460.

FIPS 140-2 and Suite B

The Suite B standard is conceptually similar to FIPS 140-2, as it restricts the set of enabled cryptographic algorithms in order to provide an assured level of security. The Suite B CipherSpecs currently supported can be used when IBM MQ is configured for FIPS 140-2 compliant operation. It is therefore possible to configure IBM MQ for both FIPS and Suite B compliance simultaneously, in which case both sets of restrictions apply.

The following diagram illustrates the relationship between these subsets:



All WebSphere MQ CipherSpecs
FIPS compliant CipherSpecs
Suite B 128-bit compliant CipherSpecs
Suite B 192-bit

Configuring IBM MQ for Suite B compliant operation

For information about how to configure IBM MQ on Windows, UNIX and Linux for Suite B compliant operation, see "Configuring IBM MQ for Suite B."

IBM MQ does not support Suite B compliant operation on the IBM i and z/OS platforms. The IBM MQ Java and JMS clients also do not support Suite B compliant operation.

Related concepts:

"Specifying that only FIPS-certified CipherSpecs are used at run time on the MQI client" on page 653
Create your key repositories using FIPS-compliant software, then specify that the channel must use FIPS-certified CipherSpecs.

Configuring IBM MQ for Suite B:

IBM MQ can be configured to operate in compliance with the NSA Suite B standard on Windows, UNIX and Linux platforms.

Suite B restricts the set of enabled cryptographic algorithms in order to provide an assured level of security. IBM MQ can be configured to operate in compliance with Suite B to provide an enhanced level of security. For further information on Suite B, see "National Security Agency (NSA) Suite B Cryptography" on page 394. For more information about Suite B configuration and its effect on SSL and TLS channels, see "NSA Suite B Cryptography in IBM MQ" on page 415.

Queue manager

For a queue manager, use the command **ALTER QMGR** with the parameter **SUITEB** to set the values appropriate for your required level of security. For further information see ALTER QMGR.

You can also use the PCF **MQCMD_CHANGE_Q_MGR** command with the **MQIA_SUITE_B_STRENGTH** parameter to configure the queue manager for Suite B compliant operation.

Note: If you alter a queue manager's Suite B settings, you must restart the MQXR service for those settings to take effect.

MQI client

By default, MQI clients do not enforce Suite B compliance. You can enable the MQI client for Suite B compliance by executing one of the following options:

1. By setting the **EncryptionPolicySuiteB** field in the MQSCO structure on an MQCONNX call to one or more of the following values:
   - MQ_SUITE_B_NONE
   - MQ_SUITE_B_128_BIT
   - MQ_SUITE_B_192_BIT

   Using MQ_SUITE_B_NONE with any other value is invalid.
2. By setting the MQSUITEB environment variable to one or more of the following values:
   - NONE
   - 128_BIT
   - 192_BIT

   You can specify multiple values using a comma separated list. Using the value NONE with any other value is invalid.
3. By setting the **EncryptionPolicySuiteB** attribute in the SSL stanza of the MQI client configuration file to one or more of the following values:
   - NONE

- 128_BIT
- 192_BIT

You can specify multiple values using a comma separated list. Using NONE with any other value is invalid.

Note: The MQI client settings are listed in order of priority. The MSCO structure on the MQCONNX call overrides the setting on the MQSUITEB environment variable, which overrides the attribute in the SSL stanza.

For full details of the MQSCO structure, see MQSCO - SSL configuration options.

For more information about the use of Suite B in the client configuration file, see SSL stanza of the client configuration file.

For further information on the use of the MQSUITEB environment variable, see Environment Variables.

.NET

For .NET unmanaged clients, the property **`MQC.ENCRYPTION_POLICY_SUITE_B`** indicates the type of Suite B security required.

For information about the using Suite B in IBM MQ classes for .NET, see MQEnvironment .NET class.

V 8.0.0.4

AMQP

The Suite B attribute settings for a queue manager apply to AMQP channels on that queue manager. If you modify the queue manager Suite B settings, you must restart the AMQP service for the changes to take effect.

Certificate validation policies in IBM MQ:

The certificate validation policy determines how strictly the certificate chain validation conforms to industry security standards.

The certificate validation policy depends upon the platform and environment as follows:
- For Java and JMS applications on all platforms, the certificate validation policy depends on the JSSE component of the Java runtime environment. For more information about the certificate validation policy, see the documentation for your JRE.
- For IBM i systems, the certificate validation policy depends on the secure sockets library provided by the operating system. For more information about the certificate validation policy, see the documentation for the operating system.
- For z/OS systems, the certificate validation policy depends on the System SSL component provided by the operating system. For more information about the certificate validation policy, see the documentation for the operating system.
- For UNIX, Linux, and Windows systems, the certificate validation policy is supplied by GSKit and can be configured. Two different certificate validation policies are supported:
  - A legacy certificate validation policy, used for maximum backwards compatibility and interoperability with old digital certificates that do not comply with the current IETF certificate validation standards. This policy is known as the Basic policy.
  - A strict, standards-compliant certificate validation policy which enforces the RFC 5280 standard. This policy is known as the Standard policy.

For information about how to configure the certificate validation policy on UNIX, Linux, and Windows systems, see "Configuring certificate validation policies in IBM MQ." For more information about the differences between the Basic and Standard certificate validation policies, see Certificate validation and trust policy design on UNIX, Linux and Windows systems.

Configuring certificate validation policies in IBM MQ:

You can specify which SSL/TLS certificate validation policy is used to validate digital certificates received from remote partner systems in four ways.

On the queue manager, the certificate validation policy can be set in the following ways:
- Using the queue manager attribute *CERTVPOL*. For more information about setting this attribute, see ALTER QMGR.

On the client, there are several methods that can be used to set the certificate validation policy. If more than one method is used to set the policy, the client uses the settings in the following priority order:
1. Using the *CertificateValPolicy* field in the client MQSCO structure. For more information about using this field, see MQSCO - SSL configuration options.
2. Using the client environment variable, *MQCERTVPOL*. For more information about using this variable, see MQCERTVPOL.
3. Using the client SSL stanza tuning parameter setting, *CertificateValPolicy*. For more information about using this setting, see SSL stanza of the client configuration file.

For more information about certificate validation policies, see "Certificate validation policies in IBM MQ" on page 418.

Digital certificates and CipherSpec compatibility in IBM MQ:

This topic provides information on how to choose appropriate CipherSpecs and digital certificates for your security policy, by outlining the relationship between CipherSpecs and digital certificates in IBM MQ.

In releases prior to IBM WebSphere MQ Version 7.1, all supported SSL and TLS CipherSpecs used the RSA algorithm for digital signatures and key agreement. All of the supported types of digital certificate were compatible with all of the supported CipherSpecs, so it was possible to change the CipherSpec for any channel without needing to change digital certificates.

In IBM WebSphere MQ Version 7.1 and later, only a subset of the supported CipherSpecs can be used with all of the supported types of digital certificate. It is therefore necessary to choose an appropriate CipherSpec for your digital certificate. Similarly, if your organization's security policy requires that you use a particular CipherSpec then you must obtain an appropriate digital certificate for that CipherSpec.

The MD5 digital signature algorithm and TLS 1.2

Digital certificates signed using the MD5 algorithm are rejected when the TLS 1.2 protocol is used. This is because the MD5 algorithm is now considered weak by many cryptographic analysts and its use is generally discouraged. If you wish to use newer CipherSpecs based on the TLS 1.2 protocol, ensure that the digital certificates do not use the MD5 algorithm in their digital signatures. Older CipherSpecs which use the SSL 3.0 and TLS 1.0 protocols are not subject to this restriction and can continue to use certificates with MD5 digital signatures.

To view the digital signature algorithm for a particular certificate, you can use the **runmqakm** command:

```
runmqakm -cert -details -db key.kdb -pw password -label cert_label
```

where *cert_label* is the certificate label of the digital signature algorithm to to display. See Digital certificate labels for details.

Note: Although the **iKeycmd (runmqckm)** tool and the **iKeyman (strmqikm)** GUI can be used to view a selection of digital signature algorithms, the **runmqakm** tool provides a wider range.

The execution of the **runmqakm** command produces output displaying the use of the signature algorithm specified:

The `Signature Algorithm` line shows that the `MD5WithRSASignature` algorithm is used. This algorithm is based upon MD5 and so this digital certificate cannot be used with the TLS 1.2 CipherSpecs.

Interoperability of Elliptic Curve and RSA CipherSpecs

Not all CipherSpecs can be used with all digital certificates. There are three types of CipherSpec, denoted by the CipherSpec name prefix. Each type of CipherSpec imposes different restrictions upon the type of digital certificate which may be used. These restrictions apply to all IBM MQ SSL and TLS connections, but are particularly relevant to users of Elliptic Curve cryptography.

The following table summarizes the relationships between CipherSpecs and digital certificates:

Table 18. Relationships between CipherSpecs and digital certificates

Type	CipherSpec Name Prefix	Description	Required public key type	Digital signature encryptionestablishment algorithm	Secret key establishment method
1	ECDHE_ECDSA_	CipherSpecs which use Elliptic Curve public keys, Elliptic Curve secret keys, and Elliptic Curve digital signature algorithms.	Elliptic Curve	ECDSA	ECDHE
2	ECDHE_RSA_	CipherSpecs which use RSA public keys, Elliptic Curve secret keys, and Elliptic Curve digital signature algorithms.	RSA	RSA	ECDHE
3	(All others)	CipherSpecs which use RSA public keys and RSA digital signature algorithms.	RSA	RSA	RSA

Note: Type 1 and 2 CipherSpecs are not supported by IBM MQ queue managers and MQI clients on the IBM i platform.

The required public key type column shows the type of public key which the personal certificate must have when using each type of CipherSpec. The personal certificate is the end-entity certificate which identifies the queue manager or client to its remote partner.

You could configure a channel with both a CipherSpec that requires an Elliptic Curve (EC) certificate, and a certificate label for an RSA certificate, or the other way round. You must ensure that the certificate named in the certificate label is appropriate for the channel CipherSpec.

Assuming that you have correctly configured IBM MQ, you can have:
- A single queue manager with a mixture of RSA and EC certificates.
- Different channels on the same queue manager using either an RSA or EC certificate.

The digital signature encryption algorithm refers to the encryption algorithm used to validate the peer. The encryption algorithm is used along with a hash algorithm such as MD5, SHA-1 or SHA-256 to compute the digital signature. There are various digital signature algorithms which can be used, for example "RSA with MD5" or "ECDSA with SHA-256". In the table, ECDSA refers to the set of digital signature algorithms which use ECDSA; RSA refers to the set of digital signature algorithms which use RSA. Any supported digital signature algorithm in the set may be used, provided it is based upon the stated encryption algorithm.

Type 1 CipherSpecs require that the personal certificate must have an Elliptic Curve public key. When these CipherSpecs are used, Elliptic Curve Diffie Hellman Ephemeral key agreement is used to establish the secret key for the connection.

Type 2 CipherSpecs require that the personal certificate has an RSA public key. When these CipherSpecs are used, Elliptic Curve Diffie Hellman Ephemeral key agreement is used to establish the secret key for the connection.

Type 3 CipherSpecs require that the the personal certificate must have an RSA public key. When these CipherSpecs are used, RSA key exchange is used to establish the secret key for the connection.

This list of restrictions is not exhaustive: depending on the configuration, there might be additional restrictions which can further affect the ability to interoperate. For example, if IBM MQ is configured to comply with the FIPS 140-2 or NSA Suite B standards then this will also limit the range of allowable configurations. Refer to the following section for more information.

If you need to use different types of CipherSpec on the same queue manager or client application, configure an appropriate certificate label and CipherSpec combination on the client definition.

The three types of CipherSpec do not interoperate directly: this is a limitation of the current SSL and TLS standards. For example, suppose you have chosen to use the ECDHE_ECDSA_AES_128_CBC_SHA256 CipherSpec for a receiver channel named TO.QM1 on a queue manager named QM1.

ECDHE_ECDSA_AES_128_CBC_SHA256 is a Type 1 CipherSpec, so the remote sender end of channel TO.QM1 must have a personal certificate with an Elliptic Curve key and an ECDSA-based digital signature. If the remote sender channel does not meet these requirements the channel fails to start.

Other channels connecting to queue manager QM1 can use other CipherSpecs, provided that each channel uses a certificate of the correct type for the CipherSpec of that channel. For example, suppose that QM1 uses a sender channel named TO.QM2 to send messages to another queue manager named QM2. The channel TO.QM2 could use the Type 3 CipherSpec TLS_RSA_WITH_AES_256_CBC_SHA256 provided both ends of the channel use certificates containing RSA public keys. The certificate label channel attribute can be used to configure a different certificate for each channel.

When planning your IBM MQ networks, consider carefully which channels require SSL or TLS, and ensure that the type of certificates used for each channel are appropriate for use with the CipherSpec on that channel.

To view the digital signature algorithm and public key type for a digital certificate you can use the **runmqakm** command:

```
runmqakm -cert -details -db key.kdb -pw password -label cert_label
```

where *cert_label* is the label of the certificate whose digital signature algorithm you need to display. See Digital certificate labels for details.

The execution of the **runmqakm** command will produce output displaying the Public Key Type:

The Public Key Type line in this case shows that the certificate has an Elliptic Curve public key. The Signature Algorithm line in this case shows that the EC_ecdsa_with_SHA384 algorithm is in use: this is based upon the ECDSA algorithm. This certificate is therefore only suitable for use with Type 1 CipherSpecs.

You can also use the **iKeycmd (runmqckm)** tool with the same parameters. Also the **iKeyman (strmqikm)** GUI can be used to view digital signature algorithms if you open the key repository and double-click the label of the certificate. However, you are advised to use the **runmqakm** tool to view digital certificates because it supports a wider range of algorithms.

Elliptic Curve CipherSpecs and NSA Suite B

When IBM MQ is configured to conform to the Suite B compliant TLS 1.2 profile, the permitted CipherSpecs and digital signature algorithms are restricted as described in “NSA Suite B Cryptography in IBM MQ” on page 415. Additionally, the range of acceptable Elliptic Curve keys is reduced according to the configured security levels.

At the 128-bit Suite B security level, the certificate subject's public key is required to use either the NIST P-256 or NIST P-384 elliptic curve and to be signed with either the NIST P-256 elliptic curve or the NIST P-384 elliptic curve. The **runmqakm** command can be used to request digital certificates for this security level using a -sig_alg parameter of EC_ecdsa_with_SHA256, or EC_ecdsa_with_SHA384.

At the 192-bit Suite B security level, the certificate subject's public key is required to use the NIST P-384 elliptic curve and to be signed with the NIST P-384 elliptic curve. The **runmqakm** command can be used to request digital certificates for this security level using a -sig_alg parameter of EC_ecdsa_with_SHA384.

The supported NIST elliptic curves are as follows:

Table 19. Supported NIST elliptic curves

NIST FIPS 186-3 curve name	RFC 4492 curve name	Elliptic Curve key size (bits)
P-256	secp256r1	256
P-384	secp384r1	384
P-521	secp521r1	521

Note: The NIST P-521 elliptic curve cannot be used for Suite B compliant operation.

Channel authentication records

To exercise more precise control over the access granted to connecting systems at a channel level, you can use channel authentication records.

You might find that clients attempt to connect to your queue manager using a blank user ID or a high-level user ID that would allow the client to perform undesirable actions. You can block access to these clients using channel authentication records. Alternatively, a client might assert a user ID that is valid on the client platform but is unknown or of an invalid format on the server platform. You can use a channel authentication record to map the asserted user ID to a valid user ID.

You might find a client application that connects to your queue manager and behaves badly in some way. To protect the server from the issues this application is causing, it needs to be temporarily blocked using the IP address the client application is on until such time as the firewall rules are updated or the client application is corrected. You can use a channel authentication record to block the IP address from which the client application connects.

If you have set up an administration tool such as the MQ Explorer, and a channel for that specific use, you might want to ensure that only specific client computers can use it. You can use a channel authentication record to allow the channel to be used only from certain IP addresses.

If you are just getting started with some sample applications running as clients, see Preparing and running the sample programs for an example of setting up the queue manager securely using channel authentication records.

To get channel authentication records to control inbound channels, use the MQSC command **ALTER QMGR CHLAUTH(ENABLED)**.

Channel authentication records can be created to perform the following functions:

- To block connections from specific IP addresses.
- To block connections from specific user IDs.
- To set an MCAUSER value to be used for any channel connecting from a specific IP address.
- To set an MCAUSER value to be used for any channel asserting a specific user ID.
- To set an MCAUSER value to be used for any channel having a specific SSL or TLS Distinguished Name (DN).
- To set an MCAUSER value to be used for any channel connecting from a specific queue manager.
- To block connections claiming to be from a certain queue manager unless the connection is from a specific IP address.

- To block connections presenting a certain SSL or TLS certificate unless the connection is from a specific IP address.

These uses are explained further in the following sections.

You create, modify, or remove channel authentication records using the MQSC command **`SET CHLAUTH`** or the PCF command **`Set Channel Authentication Record`**.

Note: Large numbers of channel authentication records can have a negative impact on a queue manager's performance.

Blocking IP addresses

It is normally the role of a firewall to prevent access from certain IP addresses. However, there might be occasions where you experience connection attempts from an IP address that should not have access to your IBM MQ system and must temporarily block the address before the firewall can be updated. These connection attempts might not be coming from IBM MQ channels; these connection attempts might be coming from other socket applications that are misconfigured to target your IBM MQ listener. Block IP addresses by setting a channel authentication record of type BLOCKADDR. You can specify one or more single addresses, ranges of addresses, or patterns including wildcards.

Whenever an inbound connection is refused because the IP address is blocked in this manner, an event message MQRC_CHANNEL_BLOCKED with reason qualifier MQRQ_CHANNEL_BLOCKED_ADDRESS is issued, provided that channel events are enabled and the queue manager is running. Additionally, the connection is held open for 30 seconds prior to returning the error to ensure the listener is not flooded with repeated attempts to connect that are blocked.

To block IP addresses only on specific channels, or to avoid the delay before the error is reported, set a channel authentication record of type ADDRESSMAP with the USERSRC(NOACCESS) parameter.

Whenever an inbound connection is refused for this reason, an event message MQRC_CHANNEL_BLOCKED with reason qualifier MQRQ_CHANNEL_BLOCKED_NOACCESS is issued, provided that channel events are enabled and the queue manager is running.

See “Blocking specific IP addresses” on page 762 for an example.

Blocking user IDs

To prevent certain user IDs from connecting over a client channel, set a channel authentication record of type BLOCKUSER. This type of channel authentication record applies only to client channels, not to message channels. You can specify one or more individual user IDs to be blocked, but you cannot use wildcards.

Whenever an inbound connection is refused for this reason, an event message MQRC_CHANNEL_BLOCKED with reason qualifier MQRQ_CHANNEL_BLOCKED_USERID is issued, provided that channel events are enabled.

See “Blocking specific user IDs” on page 763 for an example.

You can also block any access for specified user IDs on certain channels by setting a channel authentication record of type USERMAP with the USERSRC(NOACCESS) parameter.

Whenever an inbound connection is refused for this reason, an event message MQRC_CHANNEL_BLOCKED with reason qualifier MQRQ_CHANNEL_BLOCKED_NOACCESS is issued, provided that channel events are enabled and the queue manager is running.

See “Blocking access for a client asserted user ID” on page 766 for an example.

Blocking queue manager names

To specify that any channel connecting from a specified queue manager is to have no access, set a channel authentication record of type QMGRMAP with the USERSRC(NOACCESS) parameter. You can specify a single queue manager name or a pattern including wildcards. There is no equivalent of the BLOCKUSER function to block access from queue managers.

Whenever an inbound connection is refused for this reason, an event message MQRC_CHANNEL_BLOCKED with reason qualifier MQRQ_CHANNEL_BLOCKED_NOACCESS is issued, provided that channel events are enabled and the queue manager is running.

See “Blocking access from a remote queue manager” on page 766 for an example.

Blocking SSL or TLS DNs

To specify that any user presenting an SSL or TLS personal certificate containing a specified DN is to have no access, set a channel authentication record of type SSLPEERMAP with the USERSRC(NOACCESS) parameter. You can specify a single distinguished name or a pattern including wildcards. There is no equivalent of the BLOCKUSER function to block access for DNs.

Whenever an inbound connection is refused for this reason, an event message MQRC_CHANNEL_BLOCKED with reason qualifier MQRQ_CHANNEL_BLOCKED_NOACCESS is issued, provided that channel events are enabled and the queue manager is running.

See “Blocking access for an SSL Distinguished Name” on page 767 for an example.

Mapping IP addresses to user IDs to be used

To specify that any channel connecting from a specified IP address is to use a specific MCAUSER, set a channel authentication record of type ADDRESSMAP. You can specify a single address, a range of addresses, or a pattern including wildcards.

If you use a port forwarder, DMZ session break, or any other setup which changes the IP address presented to the queue manager, then mapping IP addresses is not necessarily suitable for your use.

See “Mapping an IP address to an MCAUSER user ID” on page 767 for an example.

Mapping queue manager names to user IDs to be used

To specify that any channel connecting from a specified queue manager is to use a specific MCAUSER, set a channel authentication record of type QMGRMAP. You can specify a single queue manager name or a pattern including wildcards.

See “Mapping a remote queue manager to an MCAUSER user ID” on page 764 for an example.

Mapping user IDs asserted by a client to user IDs to be used

To specify that if a certain user ID is used by a connection from an IBM MQ MQI client, a different, specified MCAUSER is to be used, set a channel authentication record of type USERMAP. User ID mapping does not use wildcards.

See “Mapping a client asserted user ID to an MCAUSER user ID” on page 765 for an example.

Mapping SSL or TLS DNs to user IDs to be used

To specify that any user presenting an SSL/TLS personal certificate containing a specified DN is to use a specific MCAUSER, set a channel authentication record of type SSLPEERMAP. You can specify a single distinguished name or a pattern including wildcards.

See "Mapping an SSL or TLS Distinguished Name to an MCAUSER user ID" on page 765 for an example.

Mapping queue managers, clients, or SSL or TLS DNs according to IP address

In some circumstances it might be possible for a third party to spoof a queue manager name. An SSL or TLS certificate or key database file might also be stolen and reused. To protect against these threats, you can specify that a connection from a certain queue manager or client, or using a certain DN must be connecting from a specified IP address. Set a channel authentication record of type USERMAP, QMGRMAP or SSLPEERMAP and specify the permitted IP address, or pattern of IP addresses, using the ADDRESS parameter.

See "Mapping a remote queue manager to an MCAUSER user ID" on page 764 for an example.

Interaction between channel authentication records

It is possible that a channel attempting to make a connection matches more than one channel authentication record, and that these have contradictory effects. For example, a channel might assert a user ID which is blocked by a BLOCKUSER channel authentication record, but with an SSL or TLS certificate that matches an SSLPEERMAP record that sets a different user ID. In addition, if channel authentication records use wildcards, a single IP address, queue manager name, or SSL or TLS DN might match several patterns. For example, the IP address 192.0.2.6 matches the patterns 192.0.2.0-24, 192.0.2.*, and 192.0.*.6. The action taken is determined as follows.

- The channel authentication record used is selected as follows:
  - A channel authentication record explicitly matching the channel name takes priority over a channel authentication record matching the channel name by using a wildcard.
  - A channel authentication record using an SSL or TLS DN takes priority over a record using a user ID, queue manager name, or IP address.
  - A channel authentication record using a user ID or queue manager name takes priority over a record using an IP address.
- If a matching channel authentication record is found and it specifies an MCAUSER, this MCAUSER is assigned to the channel.
- If a matching channel authentication record is found and it specifies that the channel has no access, an MCAUSER value of *NOACCESS is assigned to the channel. This value can later be changed by a security exit program.
- If no matching channel authentication record is found, or a matching channel authentication record is found and it specifies that the user ID of the channel is to be used, the MCAUSER field is inspected.
  - If the MCAUSER field is blank, the client user ID is assigned to the channel.
  - If the MCAUSER field is not blank, it is assigned to the channel.
- Any security exit program is run. This exit program might set the channel user ID or determine that access is to be blocked.
- If the connection is blocked or the MCAUSER is set to *NOACCESS, the channel ends.
- If the connection is not blocked, for any channel except a client channel, the channel user ID determined in the previous steps is checked against the list of blocked users.
  - If the user ID is in the list of blocked users, the channel ends.
  - If the user ID is not in the list of blocked users, the channel runs.

Where a number of channel authentication records match a channel name, IP address, hostname, queue manager name, or SSL or TLS DN, the most specific match is used. The match considered to be:

- The most specific is a name without wildcard characters, for example:
  - A channel name of A.B.C
  - An IP address of 192.0.2.6
  - A hostname of `hursley.ibm.com`
  - A queue manager name of 192.0.2.6
- The most generic is a single asterisk (*) that matches, for example:
  - All channel names
  - All IP addresses
  - All hostnames
  - All queue manager names
- A pattern with an asterisk at the start of a string is more generic than a defined value at the start of a string:
  - For channels, *.B.C is more generic than A.*
  - For IP addresses, *.0.2.6 is more generic than 192.*
  - For hostnames, `*.ibm.com` is more generic than `hursley.*`
  - For queue manager names, *QUEUEMANAGER is more generic than QUEUEMANAGER*
- A pattern with an asterisk at a specific place in a string is more generic than a defined value at the same place in a string, and similarly for each subsequent place in a string:
  - For channels, A.*.C is more generic than A.B.*
  - For IP addresses, 192.*.2.6 is more generic than 192.0.*.
  - For hostnames, `hursley.*.com` is more generic than `hursley.ibm.*`
  - For queue manager names, Q*MANAGER is more generic than QUEUE*
- Where two or more patterns have an asterisk at a specific place in a string, the one with fewer nodes following the asterisk is more generic:
  - For channels, A.* is more generic than A.*.C
  - For IP addresses, 192.* is more generic than 192.*.2.*.
  - For hostnames, `hurlsey.*` is more generic than `hursley.*.com`
  - For queue manager names, Q* is more generic than Q*MGR
- Additionally, for an IP address:
  - A range indicated with a hyphen (-), is more specific than an asterisk. Thus 192.0.2.0-24 is more specific than 192.0.2.*.
  - A range that is a subset of another is more specific than the larger range. Thus 192.0.2.5-15 is more specific than 192.0.2.0-24.
  - Overlapping ranges are not permitted. For example, you cannot have channel authentication records for both 192.0.2.0-15 and 192.0.2.10-20.
  - A pattern cannot have fewer than the required number of parts, unless the pattern ends with a single trailing asterisk. For example 192.0.2 is invalid, but 192.0.2.* is valid.
  - A trailing asterisk must be separated from the rest of the address by the appropriate part separator (a dot (.) for IPv4, a colon (:) for IPv6). For example, 192.0* is not valid because the asterisk is not in a part of its own.
  - A pattern can contain additional asterisks, provided that no asterisk is adjacent to the trailing asterisk. For example, 192.*.2.* is valid, but 192.0.*.* is not valid.
  - An IPv6 address pattern cannot contain a double colon and a trailing asterisk, because the resulting address would be ambiguous. For example, 2001::* could expand to 2001:0000:*, 2001:0000:0000:* and so on

- For an SSL or TLS Distinguished Name (DN), the precedence order of substrings is as follows:

Table 20. Precedence order of substrings

Order	DN substring	Name
1	SERIALNUMBER=	Certificate serial number
2	MAIL=	Email address
3	E=	Email address (Deprecated in preference to MAIL)
4	UID=, USERID=	User identifier
5	CN=	Common name
6	T=	Title
7	OU=	Organizational unit
8	DC=	Domain component
9	O=	Organization
10	STREET=	Street / First line of address
11	L=	Locality
12	ST=, SP=, S=	State or province name
13	PC=	Postal code / zip code
14	C=	Country
15	UNSTRUCTUREDNAME=	Host name
16	UNSTRUCTUREDADDRESS=	IP address
17	DNQ=	Distinguished name qualifier

Thus, if an SSL or TLS certificate is presented with a DN containing the substrings O=IBM and C=UK, IBM MQ uses a channel authentication record for O=IBM in preference to one for C=UK, if both are present.

A DN can contain multiple OUs, which must be specified in hierarchical order with the large organizational units specified first. If two DNs are equal in all respects except for their OU values, the more specific DN is determined as follows:

1. If they have different numbers of OU attributes then the DN with the most OU values is more specific. This is because the DN with more Organizational Units fully qualifies the DN in more detail and provides more matching criteria. Even if its top-level OU is a wildcard (OU=*), the DN with more OUs is still regarded as more specific overall.
2. If they have the same number of OU attributes then the corresponding pairs of OU values are compared in sequence left-to-right, where the left-most OU is the highest-level (least specific), according to the following rules.
   a. An OU with no wildcard values is the most specific because it can only match exactly one string.
   b. An OU with a single wildcard at either the beginning or end (for example, OU=ABC* or OU=*ABC) is next most specific.
   c. An OU with two wildcards for example, OU=*ABC*) is next most specific.
   d. An OU consisting only of an asterisk (OU=*) is the least specific.
3. If the string comparison is tied between two attribute values of the same specificity then whichever attribute string is longer is more specific.
4. If the string comparison is tied between two attribute values of the same specificity and length then the result is determined by a case-insensitive string comparison of the portion of the DN excluding any wildcards.

If two DNs are equal in all respects except for their DC values, the same matching rules apply as for OUs except that in DC values the left-most DC is the lowest-level (most specific) and the comparison ordering differs accordingly.

Displaying channel authentication records

To display channel authentication records, use the MQSC command **`DISPLAY CHLAUTH`** or the PCF command **`Inquire Channel Authentication Records`**. You can choose to return all records that match the supplied channel name, or you can choose an explicit match. The explicit match tells you which channel authentication record would be used if a channel attempted to make a connection from a specific IP address, from a specific queue manager or using a specific user ID, and, optionally, presenting an SSL/TLS personal certificate containing a specified DN.

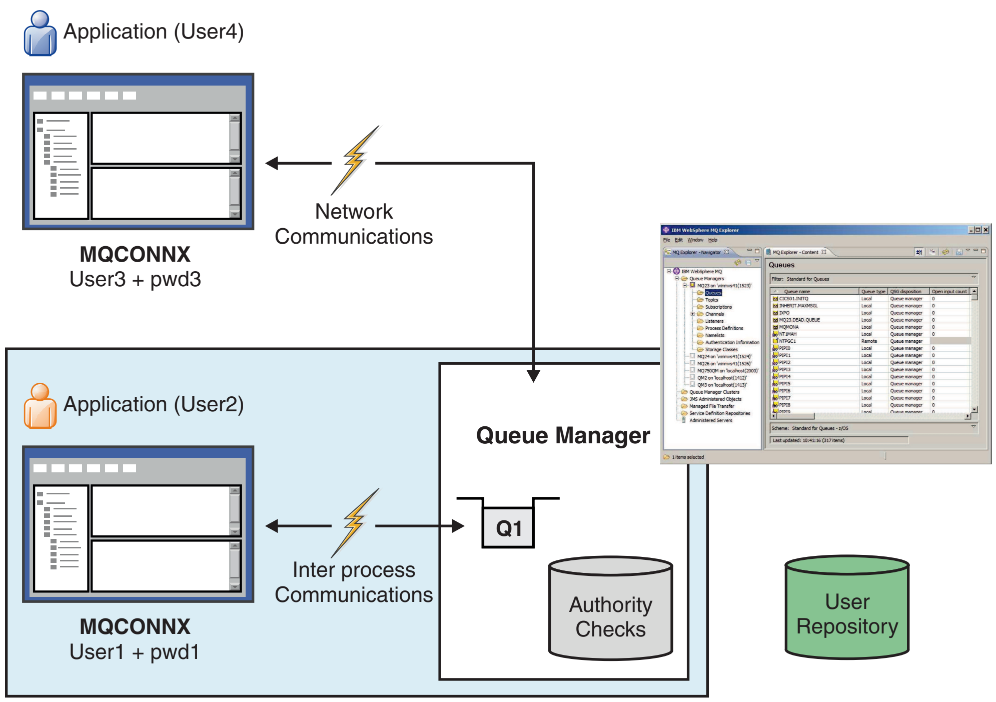
This section deals with remote messaging aspects of security.

Connection authentication

Connection authentication can be achieved in various ways:

- An application can provide a user ID and password. The application can be either a client, or it can use local bindings.
- A queue manager can be configured to act on a supplied user ID and password.
- A repository can be used to determine whether a user ID and password combination is valid.



In the diagram, two applications are making connections with a queue manager, one application as a client and one using local bindings. Applications might use a variety of APIs to connect to the queue manager, but all have the ability to provide a user ID and a password. The user ID that the application is running under, `User1` and `user3` in the diagram, which is the usual operating system user ID presented to IBM MQ, might be different from the user ID provided by the application, `User2` and `user4`.

The queue manager receives configuration commands (in the diagram, MQ Explorer is being used) and manages the opening of resources and checks the authority to access those resources. There are many different resources in IBM MQ that an application might require authority to access. The diagram illustrates opening a queue for output, but the same principles apply to other resources as well.

See User repositories for details about the repository that is used for checking user IDs and passwords.

Related concepts:

"Connection authentication: Configuration"
A queue manager can be configured to use a supplied user ID and password to check whether a user has authority to access resources.

"Connection authentication: Application changes" on page 435

"Connection authentication: User repositories" on page 436
For each of your queue managers, you can choose different types of authentication information object for authenticating user IDs and passwords.

Connection authentication: Configuration:

A queue manager can be configured to use a supplied user ID and password to check whether a user has authority to access resources.

Turning on connection authentication on a queue manager

On a queue manager object, the **CONNAUTH** attribute can be set to the name of an authentication information (AUTHINFO) object. This object can be one of two types (AUTHTYPE attribute):

IDPWOS
Indicates that the queue manager uses the local operating system to authenticate the user ID and password.

IDPWLDAP
Indicates that the queue manager uses an LDAP server to authenticate the user ID and password.

Note: You cannot use any other type of authentication information object in the **CONNAUTH** field.

IDPWOS and IDPWLDAP are similar in a number of their attributes, which are described here. Other attributes are considered later.

To check local connections, use the AUTHINFO attribute **CHCKLOCL** (check local connections). To check client connections, use the AUTHINFO attribute **CHCKCLNT** (check client connections). The configuration must be refreshed before the queue manager recognizes the changes.

```
ALTER QMGR CONNAUTH(USE.PW)
DEFINE AUTHINFO(USE.PW) +
AUTHTYPE(IDPWOS) +
FAILDLAY(10) +
CHCKLOCL(OPTIONAL) +
CHCKCLNT(REQUIRED)
REFRESH SECURITY TYPE(CONNAUTH)
```

Where `USE.PW` in the CONNAUTH is a string that matches the AUTHINFO definition.

Both **CHCKLOCL** and **CHCKCLNT** have the same set of possible values that allow the strictness of checking to be varied:

NONE Switches off checking.

OPTIONAL
Ensures that if a user ID and password are provided by an application, they are a valid pair, but that it is not mandatory to provide them. This option might be useful during migration, for example.

Important: `OPTIONAL` is the minimum value you can set, in order to use more stringent CHLAUTH rules.

If you select `NONE` and the client connection matches a CHLAUTH record with CHCKCLNT `REQUIRED` (or `REQDADM` on platforms other than z/OS), the connection fails. You receive message AMQ9793 on platforms other than z/OS, and message CSQX793E on z/OS.

REQUIRED
Requires that all applications provide a valid user ID and password. See also the following note.

REQDADM
Privileged users must supply a valid user ID and password, but non-privileged users are treated as with the `OPTIONAL` setting. See also the following note. z/OS (This setting is not allowed on z/OS systems.)

Note:

Setting **CHCKLOCL** to `REQUIRED` or `REQDADM` means that you cannot locally administer the queue manager by using **runmqsc** (error AMQ8135: Not authorized) unless the user specifies the `-u UserId` parameter on the **runmqsc** command line. With that set, **runmqsc** prompts for the user's password at the console.

Similarly, a user running IBM MQ Explorer on the local system will see error AMQ4036 when attempting to connect to the queue manager. To specify a user name and password, right-click the local queue manager object and select **Connection Details** > **Properties...** from the menu. In the **Userid** section, enter the user name and password to be used, then click **OK**.

Similar considerations apply to remote connections with **CHCKCLNT**.

CONNAUTH is blank for migrated queue managers but set to *SYSTEM.DEFAULT.AUTHINFO.IDPWOS* for new queue managers. The preceding **AUTHINFO** definition has **CHCKCLNT** set to *REQDADM* by default.

Therefore, you need to provide the correct operating system password for any existing clients using a privileged user ID to connect.

Note: In some cases, the password in an MQCSP structure for a client application will be sent across a network in plain text. To ensure that client application passwords are protected appropriately, see "MQCSP password protection" on page 404.

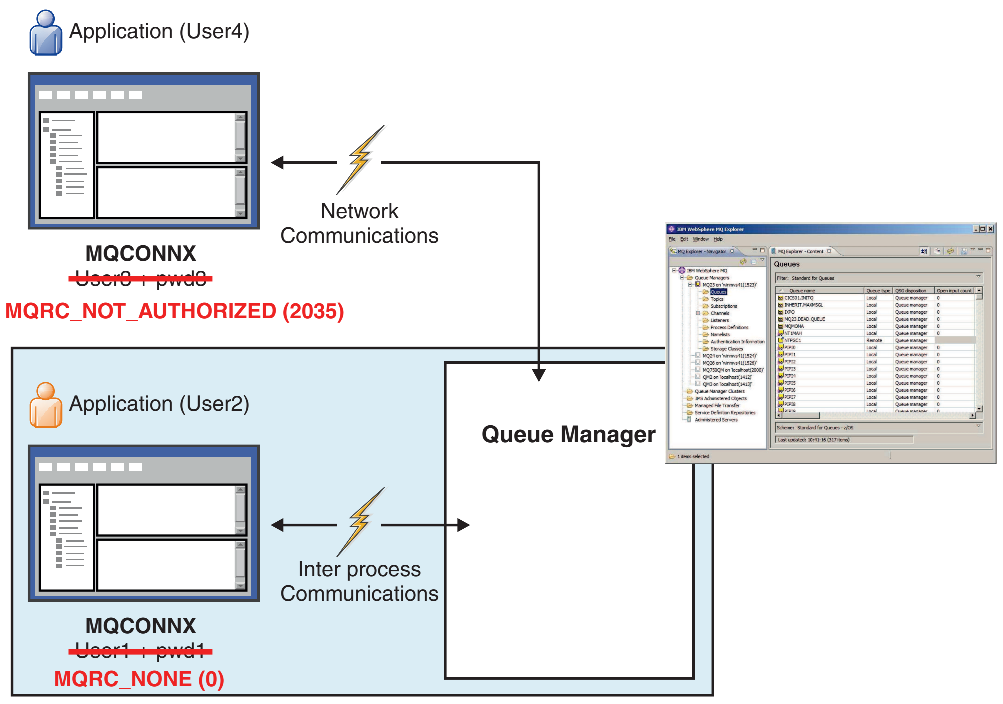
Configuration granularity

In addition to **CHCKLOCL** and **CHCKCLNT** that are used to turn on user ID and password checking, there are enhancements to the CHLAUTH rules so that more specific configuration can be made using **CHCKCLNT**.

You can set the overall **CHCKCLNT** value to `OPTIONAL`, for example, and then upgrade it to be more stringent for certain channels by setting **CHCKCLNT** to `REQUIRED` or `REQDADM` on the CHLAUTH rule. By default, CHLAUTH rules will run with CHCKCLNT(ASQMGR) so this granularity does not have to be used. For example:

```
DEFINE AUTHINFO(USE.PW) AUTHTYPE(xxxxxx) +
CHCKCLNT(OPTIONAL)
SET CHLAUTH('*') TYPE(ADDRESSMAP) +
ADDRESS('*') USERSRC(CHANNEL) +
CHCKCLNT(REQUIRED)
SET CHLAUTH('*') TYPE(SSLPEERMAP) +
SSLPEER('CN=*') USERSRC(CHANNEL)
```

Error notification



An error is recorded if an application does not supply a user ID and password when required to, or supplies an incorrect combination even when it is optional.

Note: When password checking is turned off, by using the `NONE` option on either **`CHCKLOCL`** or **`CHCKCLNT`**, invalid passwords are not detected.

Failed authentications are held for the number of seconds specified by the **`FAILDLAY`** attribute before the error is returned to the application. This provides some protection from an application repeatedly trying to connect.

The error is recorded in a number of ways:

Application
The application is returned the standard IBM MQ security error, RC2035 - MQRC_NOT_AUTHORIZED.

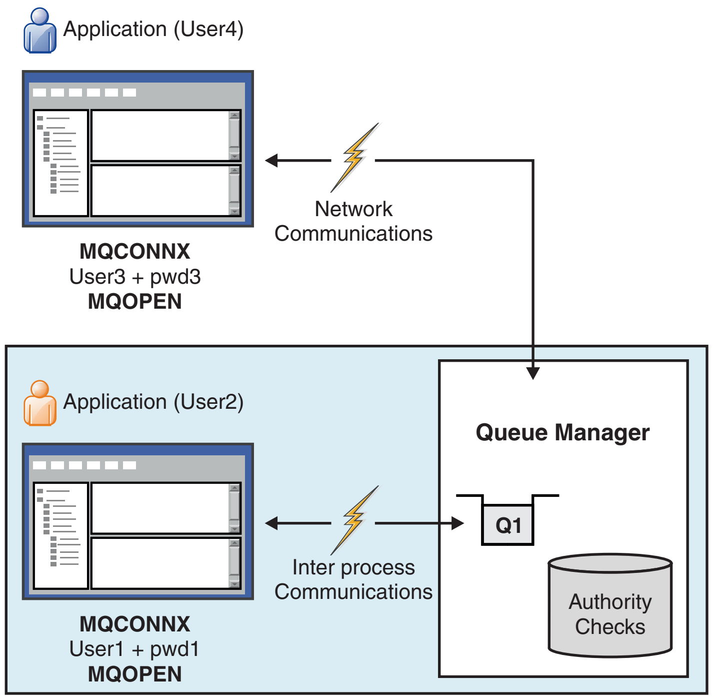
Administrator
An IBM MQ administrator sees the event reported in the error log and can therefore see that the application was rejected because the user ID and password failed the check, rather than because, for example, there was no connection authority .

Monitoring tool
A monitoring tool can also be notified of the failure, if you turn on authority events by sending an event message to the SYSTEM.ADMIN.QMGR.EVENT queue:

```
ALTER QMGR AUTHOREV(ENABLED)
```

This "Not Authorized" event is a Type 1 connect event, and provides the same fields as other Type 1 events, with an additional field, the MQCSP user ID that was provided. The password is not given in the event message. This means that there are two user IDs in the event message: the ID that the application is running under and the ID that the application presented for user ID and password checking.

Relationship to authorization



You can configure a queue manager to mandate that user IDs and passwords are provided by certain applications as the user ID that the application is running under might not be the same user ID that was presented by the application along with a password when the application opens a queue for output, for example:

```
ALTER QMGR CONNAUTH(USE.PWD)
DEFINE AUTHINFO(USE.PWD) +
AUTHTYPE(xxxxxx) +
CHCKLOCL(OPTIONAL) +
CHCKCLNT(REQUIRED) +
ADOPTCTX(YES)
```

How user IDs and passwords are handled is controlled by the **ADOPTCTX** attribute on the authentication information object.

ADOPTCTX(YES)
All authorization checks for an application are made with the same user ID that you authenticated by password, by selecting to adopt the context as the application context for the rest of the life of the connection.

ADOPTCTX(NO)
An application provides a user ID and password for the purposes of authenticating them at connection time, but then continues by using the user ID that the application is running under for future authorization checks. You might find this option useful when migrating. You might also find it useful to continue using this option, perhaps with client connections, because authorization checks are done by using an assigned message channel agent user identifier (MCAUSER) based on an IP address.

The **ADOPTCTX** setting has no effect if the user ID presented for authentication by password is the same user ID that the application is also running under.

Attention: V 8.0.0.5

When you use the **ADOPTCTX(YES)** parameter on an authentication information object, another security context cannot be adopted unless you set the **ChlauthEarlyAdopt** parameter in the channels stanza of the `qm.ini` file.

For example, the default authentication information object is set to **ADOPTCTX(YES)**, and the user `fred` is logged in. The following two CHLAUTH rules are configured:

```
SET CHLAUTH('MY.CHLAUTH') TYPE(ADDRESSMAP) DESCR('Block all access by
default') ADDRESS('*') USERSRC(NOACCESS) ACTION(REPLACE)
SET CHLAUTH('MY.CHLAUTH') TYPE(USERMAP) DESCR('Allow user bob and force
CONNAUTH') CLNTUSER('bob') CHCKCLNT(REQUIRED) USERSRC(CHANNEL)
```

The following command is issued, with the intention of authenticating the command as the adopted security context of the user `bob`:

```
runmqsc -c -u bob QMGR
```

In fact, the queue manager uses the security context of `fred`, not `bob`, and the connection fails.

For more information about **ChlauthEarlyAdopt**, see Attributes of the channels stanza.

Related concepts:

"Connection authentication" on page 430

"Connection authentication: Application changes"

"Connection authentication: User repositories" on page 436
For each of your queue managers, you can choose different types of authentication information object for authenticating user IDs and passwords.

Connection authentication: Application changes:

An application can provide a user ID and password within the connection security parameters (MQCSP) structure when MQCONNX is called. The user ID and password are passed for checking to the object authority manager (OAM) supplied with the queue manager, or the authorization service component supplied with the queue manager on z/OS systems. You do not have to write your own custom interface.

If the application is running as a client, the user ID and password are also passed to the client-side and server-side security exits for processing. They can also be used for setting the message channel agent user identifier (MCAUSER) attribute of a channel instance. The security exit is called with exit reason MQXR_SEC_PARMS for this processing. Client-side security exits and the pre-connect exit, can make changes to MQCONN before it is sent to the queue manager.

Warning: In some cases, the password in an MQCSP structure for a client application will be sent across a network in plain text. To ensure that client application passwords are protected appropriately, see "MQCSP password protection" on page 404.

By using the XAOPEN string to provide a user ID and password, you can avoid having to make changes to the application code.

Note:

From IBM WebSphere MQ Version 6.0, the security exit has allowed the MQCSP to be set. Therefore, clients at this level or later do not have to be upgraded.

However, in versions of IBM MQ prior to Version 8.0, MQCSP placed no restrictions on the user ID and password that were provided by the application. When using these values with features provided by IBM MQ there are limits which apply to the use of these features, but if you are only passing them to your own exits, those limits do not apply.

A queue manager can be configured to use a supplied user ID and password to check whether a user has authority to access resources.

"Connection authentication: User repositories"
For each of your queue managers, you can choose different types of authentication information object for authenticating user IDs and passwords.

Connection authentication: User repositories:

For each of your queue managers, you can choose different types of authentication information object for authenticating user IDs and passwords.

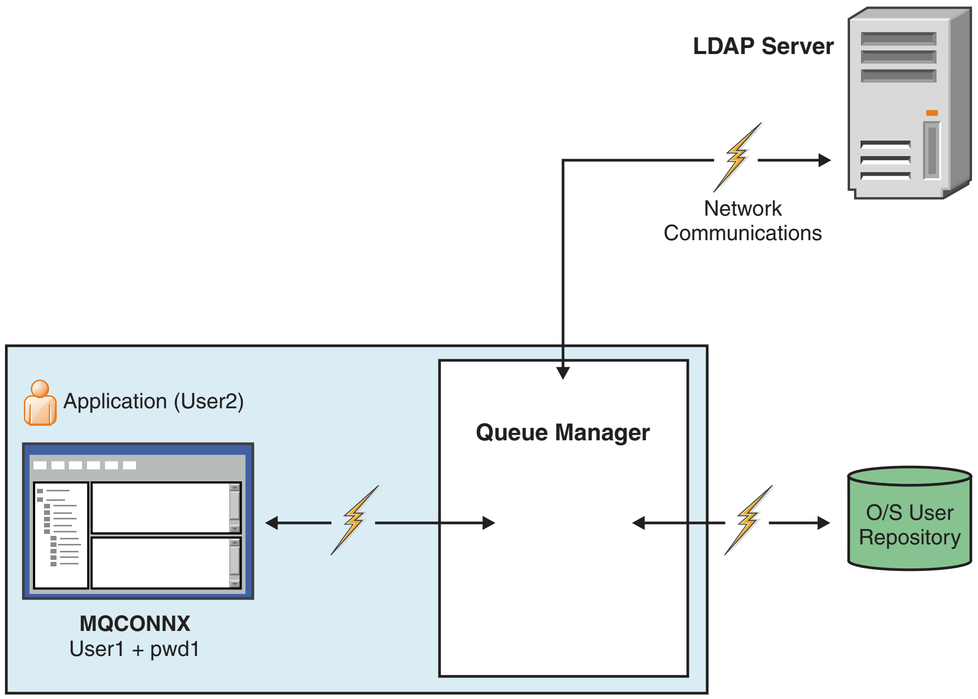

Figure 60. Types of authentication information objects

```
DEFINE AUTHINFO(USE.OS) AUTHTYPE(IDPWOS)
DEFINE AUTHINFO(USE.LDAP) +
AUTHTYPE(IDPWLDAP) +
CONNAME('ldap1(389),ldap2(389)') +
LDAPUSER('CN=QMGR1') +
LDAPPWD('passw0rd') SECCOMM(YES)
```

There are two types of authentication information object, as represented in the diagram:

- IDPWOS is used to indicate that the queue manager uses the local operating system to authentication the user ID and password. If you choose to use the local operating system, you only need to set the common attributes, as described in the preceding topics.
- IDPWLDAP is used to indicate that the queue manager uses an LDAP server to authenticate the user ID and password. If you choose to use an LDAP server, more information is provided below.

Only one type of authentication information object can be chosen for each queue manager to use, by naming the appropriate object in the queue manager's **CONNAUTH** attribute.

Using an LDAP server for authentication.

Set the **CONNAME** field to the address of the LDAP server for the queue manager. You can provide additional addresses for the LDAP server in a comma-separated list, which can help with redundancy if the LDAP server does not provide this facility itself.

Set the required LDAP server ID and password in the **LDAPUSER** and **LDAPPWD** fields so that the queue manager can access the LDAP server and look up information about user records.

Secure connection to an LDAP Server

Unlike channels, there is no **SSLCIPH** parameter to turn on the use of SSL/TLS for communication with the LDAP server. In this case IBM MQ is acting as a client to the LDAP server so much of the configuration is done at the LDAP server. Some existing parameters in IBM MQ are used to configure how that connection works.

Set the **SECCOMM** field to control whether connectivity to the LDAP server uses SSL/TLS.

In addition to this attribute, the queue manager attributes **SSLFIPS** and **SUITEB** restrict the set of cipher specs that are chosen. The certificate that is used to identify the queue manager to the LDAP server is the queue manager certificate, either `ibmwebspheremq` *<qmgr-name>* or the value of the **CERTLABL** attribute. See Digital certificate labels for details.

LDAP User Repository

When using an LDAP user repository there is some more configuration to be done on the queue manager other than just to tell the queue manager where to find the LDAP server.

User IDs defined in an LDAP server have a hierarchical structure that uniquely identifies them. An application can therefore connect to the queue manager and present its user ID as the fully qualified hierarchical user ID.

However, to simplify the information that an application has to provide, it is possible to configure the queue manager to assume that the first part of the hierarchy is common to all IDs, and to automatically add this before the shortened ID provide by the application. The queue manager can then present a complete ID to the LDAP server.

Set BASEDNU to the initial point that the LDAP search looks for the ID in the LDAP hierarchy. When you set BASEDNU, you must ensure that only one result is returned when you search for the ID in the LDAP hierarchy.

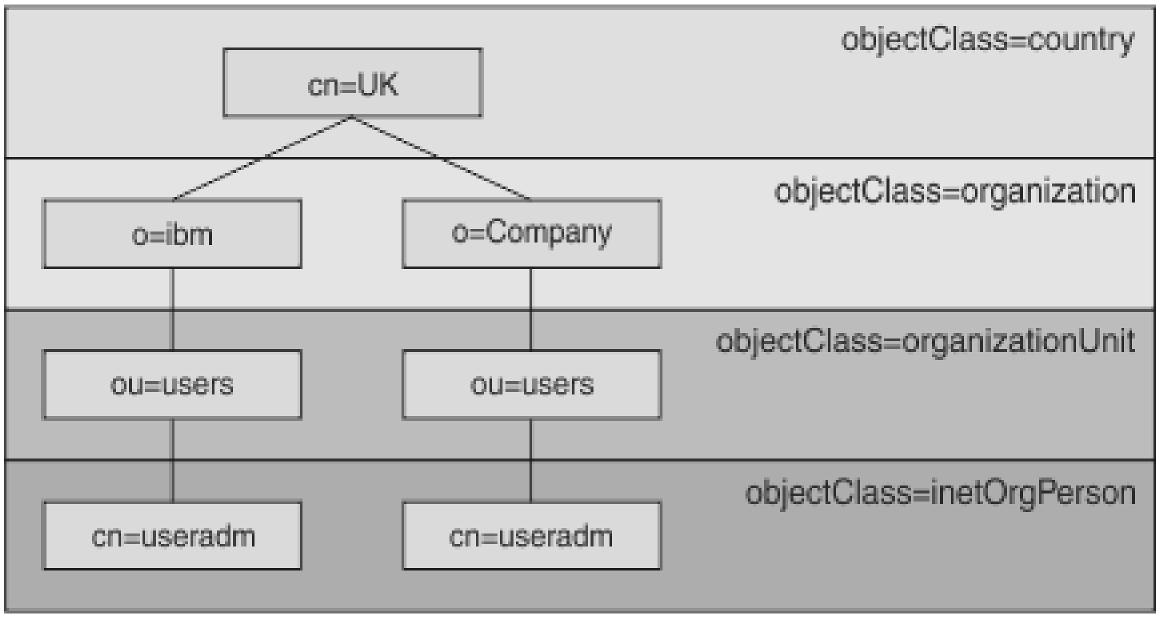

Figure 61. An example LDAP hierarchy

For example, in Figure 61 BASEDNU can be set to "ou=users,o=ibm,c=UK" or ",o=ibm,c=UK". However, because a distinguished name that contains "cn=useradm" exists in both the "o=ibm" branch and the "o=Company" branch, BASEDNU cannot be set to "c=UK". For performance and security reasons, use the highest point in your LDAP hierarchy that from which you can reference all of the userids that you need. In this example, that is "ou=users,o=ibm,c=UK".

Your application might submit to the queue manager the user ID without providing the LDAP attribute name, `CN=` for example. If you set USRFIELD to the LDAP attribute name, this value is added as a prefix to the user ID that comes from the application. This might be a useful migratory aid when moving from operating system user IDs to LDAP user IDs, as the application can then present the same string in both cases and you can avoid making changes to the application.

The complete user ID presented to the LDAP server therefore looks like this:

```
<USRFIELD> = <ID_from_application> <BASEDNU>
```

Client side security exit to insert user ID and password (`mqccred`):

If you have any client applications that are required to send a user ID or password but you are unable to change the source yet, there is a security exit shipped with IBM MQ Version 8.0 called **`mqccred`** that you can use. **`mqccred`** provides a user ID and password on behalf of the client application, from a `.ini` file. This user ID and password are sent to the queue manager which, if configured to do so, will authenticate them.

Overview

`mqccred` is a security exit that runs on the same machine as your client application. It allows user ID and password information to be supplied on behalf of the client application, where that information is not being supplied by the application itself. The user ID and password information is supplied in a structure known as the Connection Security Parameters (MQCSP) and will be authenticated by the queue manager if connection authentication is configured.

User ID and password information is retrieved from a `.ini` file on the client machine. The passwords in the file are protected by obfuscation using the **`runmqccred`** command, and also by ensuring the file permissions on the `.ini` file are set such that only the user ID running the client application (and therefore the exit) are able to read it.

Location

`mqccred` is installed:

Windows platforms
In the `<installation directory>\Tools\c\Samples\mqccred\` directory

UNIX platforms
In the `<installation_directory>/samp/mqccred` directory

Notes: The exit:

1. Acts purely as a security channel exit, and needs to be the only such exit defined on a channel.
2. Is usually named through the Client Channel Definition Table (CCDT), but a Java client can have the exit mentioned in the JNDI objects directly, or the exit might be configured for applications that manually construct the MQCD structure.
3. You must copy the **`mqccred`** and **`mqccred_r`** programs to the `var/mqm/exits` directory.

   For example, on a 64 bit UNIX platform machine, issue the command:

   ```
   cp <installation_directory>/samp/mqccred/lib64/* /var/mqm/exits
   ```

   See A step by step example of how to test mqccred for more information.
4. Is capable of running on previous versions of IBM MQ ; as far back as Version 7.0.1.

Setting up user IDs and passwords

The `.ini` file contains stanzas for each queue manager, with a global setting for unspecified queue managers. Each stanza contains the name of the queue manager, a user ID, and either a plain text or obfuscated password.

You must edit the `.ini` file by hand, using whichever editor you want, and add the plain text password attribute to the stanzas. Run the provided, **runmqccred** program, which takes the `.ini` file and replaces the **Password** attribute with the **OPW** attribute, an obfuscated form of the password.

See runmqccred for a description of the command and its parameters.

The `mqccred.ini` file contains your user ID and password information.

A template `.ini` file is provided in the same directory as the exit to provide a starting point for your enterprise.

By default, this file will be looked for in `$HOME/.mqs/mqccred.ini`. If you would like to locate it elsewhere, you can use the environment variable *MQCCRED* to point at it:

```
MQCCRED=C:\mydir\mqccred.ini
```

If you use *MQCCRED*, the variable must include the full name of the configuration file, including any `.ini` filetype. Since this file contains passwords (even if obfuscated), you are expected to protect the file using operating system privileges to ensure unauthorized people cannot read it. If you do not have the correct file permission, the exit will not run successfully.

If the application has already supplied an MQCSP structure, the exit normally respects this and will not insert any information from the `.ini` file. However, you can override this by using the **Force** attribute in the stanza.

Setting **Force** to the value *TRUE* removes the application-supplied user ID and password, and replaces those with the ini file version.

You can also set the **Force** attribute in the global section of the file to set the default value of that file.

The default value for **Force** is *FALSE*.

You can provide a user ID and password for all queue managers, or for each individual queue manager. This is an example of an `mqccred.ini` file:

```
# comments are permitted
AllQueueManagers:
User=abc
OPW=%^&aervrgtsr

QueueManager:
Name=QMA
User=user1
OPW=H&^dbgfh

Force=TRUE

QueueManager:
Name=QMB
User=user2
password=passw0rd
```

Notes:

1. The individual queue manager definitions take precedence over the global setting.

2. Attributes are case insensitive.

Constraints

When this exit is in use, the local user ID of the person running the application does not flow from the client to the server. The only identity information available is from the ini file contents.

Therefore, you must configure the queue manager to either use **ADOPTCTX(YES)**, or map the inbound connection request to an appropriate user ID through one of the available mechanisms, for example, "Channel authentication records" on page 424.

Important: If you add new passwords, or update old ones, the **runmqccred** command only processes any plain text passwords, leaving your obfuscated ones untouched.

Debugging

The exit writes to the standard IBM MQ trace when that is enabled.

To assist in debugging configuration issues, the exit can also write directly to stdout.

No channel security exit data (**SCYDATA**) configuration is normally required for the channel. However, you can specify:

ERROR
: Only print information abut error conditions, such as not being able to find the configuration file.

DEBUG
: Displays these error conditions, and some additional trace statements.

NOCHECKS
: Bypasses the constraints on file permissions, and the further constraint that the `.ini` file should not contain any unprotected passwords.

You can put one or more of these elements into the **SCYDATA** field, separated by commas, in any order. For example, `SCYDATA=(NOCHECKS,DEBUG)`.

Note that the items are case-sensitive, and must be entered in uppercase.

Using `mqccred`

Once you have your file set up, you can invoke the channel exit by updating your client-connection channel definition to include the `SCYEXIT('mqccred(ChlExit)')` attribute:

```
DEFINE CHANNEL(<channelname>) CHLTYPE(clntconn) +
CONNAME(<remote machine>) +
QMNAME(<remote qmgr>) +
SCYEXIT('mqccred(ChlExit)') +
REPLACE
```

Related information:
SCYDATA
SCYEXIT
runmqccred

Connection authentication with the Java client:

Connection authentication is a feature in IBM MQ that allows the queue manager to be configured, to authenticate applications, using a provided user ID and password. When the application is a Java application using client bindings, there are two modes in which this can be run.

Compatibility mode

In releases prior to IBM MQ Version 8.0, the Java client could send a user ID and password across the client-connection channel to the server-connection channel, and have them provided to a security exit in the **`RemoteUserIdentifier`** and **`RemotePassword`** fields of the MQCD structure. In compatibility mode, this behavior is retained.

You might use this mode in combination with connection authentication, and migrate away from any security exits that were previously used to do the same job.

You must use ADOPTCTX(YES) or have another method, for example a CHLAUTH rule based on an SSL/TLS certificate, to set the running MCAUSER when using compatibility mode, as in this mode, the client side user ID is not sent to the queue manager.

Compatibility mode is the default setting.

MQCSP authentication mode

In this mode, the client side user ID is sent as well as the user ID and password to be authenticated, so you are able to use ADOPTCTX(NO). The user ID and password are available to a server-connection security exit in the MQCSP structure provided in the MQCXP structure.

This mode of operation can be enabled on a connection-by-connection basis or globally:
- In IBM MQ classes for Java, set the property *MQConstants.USE_MQCSP_AUTHENTICATION_PROPERTY* to **true** in the properties hashtable passed to the **`com.ibm.mq.MQQueueManager`** constructor.
- In IBM MQ classes for JMS, set the property *JmsConstants.USER_AUTHENTICATION_MQCSP* to **true**, on the appropriate connection factory prior to creating the connection.
- Globally, set the system property *com.ibm.mq.cfg.jmqi.useMQCSPauthentication* to a value indicating true, for example, by adding `-Dcom.ibm.mq.cfg.jmqi.useMQCSPauthentication=Y` to the command line.

Enabling MQCSP Authentication mode in IBM MQ Explorer

The MQ Explorer is a Java application, so these two modes are applicable to it as well.

As for other Java applications, compatibility mode is the default.

On panels where user identification is provided, there is a check box to enable or disable compatibility mode.

By default, this check box is enabled. To use MQCSP Authentication, remove the check mark from this box.

For each of your queue managers, you can choose different types of authentication information object for authenticating user IDs and passwords.

Message security in IBM MQ

Message security in IBM MQ infrastructure is provided by a separately licensed component IBM MQ Advanced Message Security.

IBM MQ Advanced Message Security (IBM MQ AMS) expands IBM MQ security services to provide data signing and encryption at the message level. The expanded services guarantees that message data has not been modified between when it is originally placed on a queue and when it is retrieved. In addition, IBM MQ AMS verifies that a sender of message data is authorized to place signed messages on a target queue.

"IBM MQ Advanced Message Security" on page 849
IBM MQ Advanced Message Security (IBM MQ AMS) is a separately licensed component of IBM MQ that provides a high level of protection for sensitive data flowing through the IBM MQ network, while not impacting the end applications.

Planning for your security requirements

This collection of topics explains what you need to consider when planning security in an IBM MQ environment.

You can use IBM MQ for a wide variety of applications on a range of platforms. The security requirements are likely to be different for each application. For some, security will be a critical consideration.

IBM MQ provides a range of link-level security services, including support for the Secure Sockets Layer (SSL) and Transport Layer Security (TLS).

You must consider certain aspects of security when implementing WebSphere. On IBM i IBM i, UNIX, Linux and Windows systems, if you ignore these aspects and do nothing, you cannot use IBM MQ. z/OS On z/OS, the effect of ignoring these aspects is that your IBM MQ resources are unprotected. That is, all users can access and change all IBM MQ resources.

Authority to administer IBM MQ

IBM MQ administrators need authority to:

- Issue commands to administer IBM MQ
- Use the IBM MQ Explorer
- z/OS Use the operations and control panels on z/OS
- IBM i Use IBM i administrative panels and commands.
- z/OS Use the IBM MQ utility program, CSQUTIL, on z/OS
- z/OS Access the queue manager data sets on z/OS

For more information, see:

- "Authority to administer IBM MQ on UNIX, Linux, and Windows systems" on page 777
- IBM i "Authority to administer IBM MQ on IBM i" on page 449
- z/OS "Authority to administer IBM MQ on z/OS" on page 450

Authority to work with IBM MQ objects

Applications can access the following IBM MQ objects by issuing MQI calls:

- Queue managers
- Queues
- Processes
- Namelists
- Topics

Applications can also use Programmable Command Format (PCF) commands to access these IBM MQ objects, and to access channels and authentication information objects as well. These objects can be protected by IBM MQ so that the user IDs associated with the applications need authority to access them.

For more information, see "Authorization for applications to use IBM MQ" on page 452.

Channel security

The user IDs associated with message channel agents (MCAs) need authority to access various IBM MQ resources. For example, an MCA must be able to connect to a queue manager. If it is a sending MCA, it must be able to open the transmission queue for the channel. If it is a receiving MCA, it must be able to open destination queues. The user IDs associated with applications which need to administer channels, channel initiators, and listeners need authority to use the relevant PCF commands. However, most applications do not need such access.

For more information, see "Channel authorization" on page 485.

Additional considerations

You need to consider the following aspects of security only if you are using certain IBM MQ function or base product extensions:

- "Security for queue manager clusters" on page 499
- "Security for IBM MQ Publish/Subscribe" on page 501
- "Security for IBM MQ internet pass-thru" on page 505

Planning identification and authentication

Decide what user IDs to use, and how and at what levels you want to apply authentication controls.

You must decide how you will identify the users of your IBM MQ applications, bearing in mind that different operating systems support user IDs of different lengths. You can use channel authentication records to map from one user ID to another, or to specify a user ID based on some attribute of the connection. IBM MQ channels using SSL or TLS use digital certificates as a mechanism for identification and authentication. Each digital certificate has a subject distinguished name which can be mapped onto specific identities using channel authentication records. Additionally, CA certificates in the key repository determine which digital certificates may be used to authenticate to IBM MQ. For more information see:

- "Mapping a remote queue manager to an MCAUSER user ID" on page 764
- "Mapping a client asserted user ID to an MCAUSER user ID" on page 765
- "Mapping an SSL or TLS Distinguished Name to an MCAUSER user ID" on page 765
- "Mapping an IP address to an MCAUSER user ID" on page 767

Planning authentication for a client application

You can apply authentication controls at four levels: at the communications level, in security exits, with channel authentication records, and in terms of the identification that is passed to a security exit.

There are four levels of security to consider. The diagram shows an IBM MQ MQI client that is connected to a server. Security is applied at four levels, as described in the following text. MCA is a Message Channel Agent.

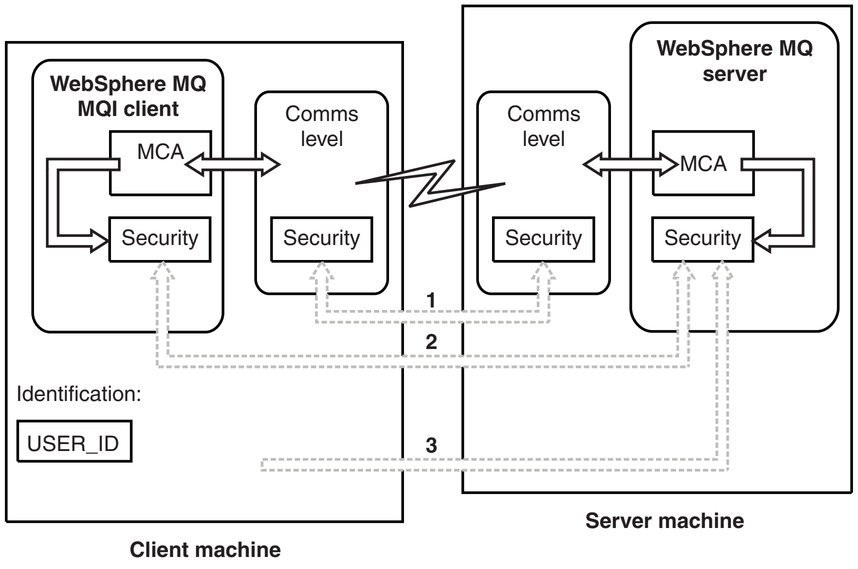

Figure 62. Security in a client/server connection

1. Communications level

   See arrow 1. To implement security at the communications level, use SSL or TLS. For more information, see "Cryptographic security protocols: SSL and TLS" on page 388
2. Channel authentication records

   See arrows 2 & 3. Authentication can be controlled by using the IP address or SSL/TLS distinguished names at the security level. A user ID can also be blocked or an asserted user ID can be mapped to a valid user ID. A full description is given in "Channel authentication records" on page 424.
3. Connection authentication

   See arrow 3. The client sends an ID and a password. For more information, see “Connection authentication: Configuration” on page 431.
4. Channel security exits

   See arrow 2. The channel security exits for client to server communication can work in the same way as for server to server communication. A protocol independent pair of exits can be written to provide mutual authentication of both the client and the server. A full description is given in Channel security exit programs.
5. Identification that is passed to a channel security exit

   See arrow 3. In client to server communication, the channel security exits do not have to operate as a pair. The exit on the IBM MQ client side can be omitted. In this case, the user ID is placed in the channel descriptor (MQCD) and the server-side security exit can alter it, if required.

   Windows clients also send extra information to assist identification.
   - The user ID that is passed to the server is the currently logged-on user ID on the client.
   - The security ID of the currently logged-on user.

   To assist identification on IBM MQ client for HP Integrity NonStop Server, the client passes the OSS Safeguard alias under which the client application is running. This ID is typically of the form `<PRIMARYGROUP>.<ALIAS>`. If required, you can map this user ID to an alternative user ID on the queue manager by using either channel authentication records or a security exit. For more information about message exits, see “Identity mapping in message exits” on page 720. For more information about defining channel authentication records, see “Mapping a client asserted user ID to an MCAUSER user ID” on page 765.

   The values of the user ID and, if available, the security ID, can be used by the server security exit to establish the identity of the IBM MQ MQI client.

From IBM MQ Version 8.0, you can send passwords that are included in the MQCSP structure.

Warning: In some cases, the password in an MQCSP structure for a client application will be sent across a network in plain text. To ensure that client application passwords are protected appropriately, see “MQCSP password protection” on page 404.

User IDs:

When you create user IDs for client applications, the user IDs must not be longer than the maximum permitted length. You must not use the reserved user IDs UNKNOWN and NOBODY. If the server that the client connects to is an IBM MQ for Windows server, you must escape the use of the at sign, @. The permitted length of user IDs is dependent on the platform that is used for the server:
- On z/OS and UNIX and Linux, the maximum length of a user ID is 12 characters.
- IBM i On IBM i, the maximum length of a user ID is 10 characters.
- On Windows, if both the IBM MQ MQI client, and the IBM MQ server are on Windows, and the server has access to the domain on which the client user ID is defined, the maximum length of a user ID is 20 characters. However, if the IBM MQ server is not a Windows server, the user ID is truncated to 12 characters. You can use the MQCSP structure to avoid the truncation of the user ID.
- If you use the MQCSP structure to pass credentials, the maximum length of a user ID is 1024 characters. For more information about the MQCSP structure, see “Identifying and authenticating users using the MQCSP structure” on page 718.

Although user IDs are used to authenticate, groups are used for authorization, except for Windows.

If you create service accounts, without paying attention to groups, and authorize all the user IDs differently, every user can access the information of every other user.

Restricted user IDs

The user IDs `UNKNOWN` and `NOBODY` have special meanings to IBM MQ. Creating user IDs in the operating system called `UNKNOWN` or `NOBODY` could have unintended results.

User IDs when connecting to an IBM MQ for Windows server

An IBM MQ for Windows server does not support the connection of a Windows client if the client is running under a user ID that contains the @ character, for example, `abc@d`. The return code to the **MQCONN** call at the client is MQRC_NOT_AUTHORIZED.

However, you can specify the user ID using two @ characters, for example, `abc@@d`. Using the `id@domain` format is the preferred practice, to ensure that the user ID is resolved in the correct domain consistently; thus `abc@@d@domain`.

Planning authorization

Plan the users who will have administrative authority and plan how to authorize users of applications to appropriately use IBM MQ objects, including those connecting from an IBM MQ MQI client.

Individuals or applications must be granted access in order to use IBM MQ. What access they require depend on the roles they undertake and the tasks which they need to perform. Authorization in IBM MQ can be subdivided into two main categories:

- Authorization to perform administrative operations
- Authorization for applications to use IBM MQ

Both classes of operation are controlled by the same component and an individual can be granted authority to perform both categories of operation.

The following topics give further information about specific areas of authorization that you must consider:

Authority to administer IBM MQ

IBM MQ administrators need authority to perform various functions. This authority is obtained in different ways on different platforms.

IBM MQ administrators need authority to:

- Issue commands to administer IBM MQ
- Use the IBM MQ Explorer
- z/OS Use the operations and control panels on z/OS
- z/OS Use the IBM MQ utility program, CSQUTIL, on z/OS
- z/OS Access the queue manager data sets on z/OS

For more information, see the topic appropriate to your operating system.

Authority to administer IBM MQ on UNIX and Windows systems:

An IBM MQ administrator is a member of the mqm group. This group has access to all IBM MQ resources and can issue IBM MQ control commands. An administrator can grant specific authorities to other users.

To be an IBM MQ administrator on UNIX and Windows systems, a user must be a member of the *mqm group*. This group is created automatically when you install IBM MQ. To allow users to issue control commands, you must add them to the mqm group. This includes the root user on UNIX systems.

Users who are not member of the mqm group can be granted administrative privileges, but they are not able to issue IBM MQ control commands, and they are authorized to execute only the commands for which they have been granted access.

Additionally, on Windows systems, the SYSTEM and Administrator accounts have full access to IBM MQ resources.

All members of the mqm group have access to all IBM MQ resources on the system, including being able to administer any queue manager running on the system. This access can be revoked only by removing a user from the mqm group. On Windows systems, members of the Administrators group also have access to all IBM MQ resources.

Administrators can use the control command **runmqsc** to issue IBM MQ Script (MQSC) commands. When **runmqsc** is used in indirect mode to send MQSC commands to a remote queue manager, each MQSC command is encapsulated within an Escape PCF command. Administrators must have the required authorities for the MQSC commands to be processed by the remote queue manager.

The IBM MQ Explorer issues PCF commands to perform administration tasks. Administrators require no additional authorities to use the IBM MQ Explorer to administer a queue manager on the local system. When the IBM MQ Explorer is used to administer a queue manager on another system, administrators must have the required authorities for the PCF commands to be processed by the remote queue manager.

For more information about the authority checks carried out when PCF and MQSC commands are processed, see the following topics:
- For commands that operate on queue managers, queues, channels, processes, namelists, and authentication information objects, see "Authorization for applications to use IBM MQ" on page 452.
- For commands that operate on channels, channel initiators, listeners, and clusters, see Channel security.
- z/OS For MQSC commands that are processed by the command server on IBM MQ for z/OS, see "Command security and command resource security" on page 450.

For more information about the authority you need to administer IBM MQ on UNIX and Windows systems, see the related information.

Authority to administer IBM MQ on IBM i:

To be an IBM MQ administrator on IBM i, you must be a member of the *QMQMADM group*. This group has properties similar to those of the mqm group on UNIX and Windows systems. In particular, the QMQMADM group is created when you install IBM MQ for IBM i, and members of the QMQMADM group have access to all IBM MQ resources on the system. You also have access to all IBM MQ resources if you have *ALLOBJ authority.

Administrators can use CL commands to administer IBM MQ. One of these commands is GRTMQMAUT, which is used to grant authorities to other users. Another command, STRMQMMQSC, enables an administrator to issue MQSC commands to a local queue manager.

There are two groups of CL command provided by IBM MQ for IBM i:

Group 1
: To issue a command in this category, a user must be a member of the QMQMADM group or have *ALLOBJ authority. GRTMQMAUT and STRMQMMQSC belong to this category, for example.

Group 2
: To issue a command in this category, a user does not need to be a member of the QMQMADM group or have *ALLOBJ authority. Instead, two levels of authority are required:

  - The user requires IBM i authority to use the command. This authority is granted by using the GRTOBJAUT command.
  - The user requires IBM MQ authority to access any IBM MQ object associated with the command. This authority is granted by using the GRTMQMAUT command.

  The following are examples of commands in this group:

  - CRTMQMQ, Create MQM Queue
  - CHGMQMPRC, Change MQM Process
  - DLTMQMNL, Delete MQM Namelist
  - DSPMQMAUTI, Display MQM Authentication Information
  - CRTMQMCHL, Create MQM channel

  For more information about this group of commands, see “Authorization for applications to use IBM MQ” on page 452.

For a complete list of group 1 and group 2 commands, see “Access authorities for IBM MQ objects on IBM i” on page 540

For more information about the authority you need to administer IBM MQ on IBM i, see Administering IBM i .

Authority to administer IBM MQ on z/OS:

This collection of topics describes various aspects of the authority you need to administer IBM MQ for z/OS.

Authority checks on z/OS:

IBM MQ uses the System Authorization Facility (SAF) to route requests for authority checks to an external security manager (ESM) such as the z/OS Security Server Resource Access Control Facility (RACF). IBM MQ does no authority checks of its own.

It is assumed that you are using RACF as your ESM. If you are using a different ESM, you might need to interpret the information provided for RACF in a way that is relevant to your ESM.

You can specify whether you want authority checks turned on or off for each queue manager individually or for every queue manager in a queue-sharing group. This level of control is called *subsystem security*. If you turn subsystem security off for a particular queue manager, no authority checks are carried out for that queue manager.

If you turn subsystem security on for a particular queue manager, authority checks can be performed at two levels:

Queue-sharing group level security
Authority checks use RACF profiles that are shared by all queue managers in the queue-sharing group. This means that there are fewer profiles to define and maintain, making security administration easier.

Queue manager level security
Authority checks use RACF profiles specific to the queue manager.

You can use a combination of queue-sharing group and queue manager level security. For example, you can arrange for profiles specific to a queue manager to override those of the queue-sharing group to which it belongs.

Subsystem security, queue-sharing group level security, and queue manager level security are turned on or off by defining *switch profiles*. A switch profile is a normal RACF profile that has a special meaning to IBM MQ.

Command security and command resource security:

Command security relates to the authority to issue a command; command resource authority relates to the authority to perform an operation on a resource. Both are implemented y using RACF classes.

Authority checks are carried out when an IBM MQ administrator issues an MQSC command. This is called *command security*.

To implement command security, you must define certain RACF profiles and give the necessary groups and user IDs access to these profiles at the required levels. The name of a profile for command security contains the name of an MQSC command.

Some MQSC commands perform an operation on an IBM MQ resource, such as the DEFINE QLOCAL command to create a local queue. When an administrator issues an MQSC command, authority checks are carried out to determine whether the requested operation can be performed on the resource specified in the command. This is called *command resource security*.

To implement command resource security, you must define certain RACF profiles and give the necessary groups and user IDs access to these profiles at the required levels. The name of a profile for command resource security contains the name of an IBM MQ resource and its type (QUEUE, PROCESS, NAMELIST, TOPIC, AUTHINFO, or CHANNEL).

Command security and command resource security are independent. For example, when an administrator issues the command:

```
DEFINE QLOCAL(MOON.EUROPA)
```

the following authority checks are performed:

- Command security checks that the administrator is authorized to issue the DEFINE QLOCAL command.
- Command resource security checks that the administrator is authorized to perform an operation on the local queue called MOON.EUROPA.

Command security and command resource security can be turned on or off by defining switch profiles.

MQSC commands and the system command input queue:

Use this topic to understand how the command server processes MQSC commands directed to the system command input queue.

Command security and command resource security are also used when the command server retrieves a message containing an MQSC command from the system command input queue. The user ID that is used for the authority checks is the one found in the *UserIdentifier* field in the message descriptor of the message containing the MQSC command. This user ID must have the required authorities on the queue manager where the command is processed. For more information about the *UserIdentifier* field and how it is set, see Message context.

Messages containing MQSC commands are sent to the system command input queue in the following circumstances:

- The operations and control panels send MQSC commands to the system command input queue of the target queue manager. The MQSC commands correspond to the actions you choose on the panels. The *UserIdentifier* field in each message is set to the TSO user ID of the administrator.
- The COMMAND function of the IBM MQ utility program, CSQUTIL, sends the MQSC commands in the input data set to the system command input queue of the target queue manager. The COPY and EMPTY functions send DISPLAY QUEUE and DISPLAY STGCLASS commands. The *UserIdentifier* field in each message is set to the job user ID.
- The MQSC commands in the CSQINPX data sets are sent to the system command input queue of the queue manager to which the channel initiator is connected. The *UserIdentifier* field in each message is set to the channel initiator address space user ID.

  No authority checks are performed when MQSC commands are issued from the CSQINP1 and CSQINP2 data sets. You can control who is allowed to update these data sets using RACF data set protection.
- Within a queue-sharing group, a channel initiator might send START CHANNEL commands to the system command input queue of the queue manager to which it is connected. A command is sent when an outbound channel that uses a shared transmission queue is started by triggering. The *UserIdentifier* field in each message is set to the channel initiator address space user ID.
- An application can send MQSC commands to a system command input queue. By default, the *UserIdentifier* field in each message is set to the user ID associated with the application.
- On UNIX, Linux and Windows systems, the **runmqsc** control command can be used in indirect mode to send MQSC commands to the system command input queue of a queue manager on z/OS. The *UserIdentifier* field in each message is set to the user ID of the administrator who issued the **runmqsc** command.

Access to the queue manager data sets:

IBM MQ administrators need authority to access the queue manager data sets. Use this topic to understand which data sets need RACF protection.

These data sets include:
- The data sets referred to by CSQINP1, CSQINP2, CSQINPT, and CSQXLIB in the queue manager's started task procedure
- The queue manager's page sets, active log data sets, archive log data sets, and bootstrap data sets (BSDSs)
- The data sets referred to by CSQXLIB and CSQINPX in the channel initiator's started task procedure

You must protect the data sets so that no unauthorized user can start a queue manager or gain access to any queue manager data. To do this, use RACF data set protection.

Authorization for applications to use IBM MQ

When applications access objects, the user IDs associated with the applications need appropriate authority.

Applications can access the following IBM MQ objects by issuing MQI calls:
- Queue managers
- Queues
- Processes
- Namelists
- Topics

Applications can also use PCF commands to administer IBM MQ objects. When the PCF command is processed, it uses the authority context of the user ID that put the PCF message.

Applications, in this context, include those written by users and vendors, and those supplied with IBM MQ for z/OS. The applications supplied with IBM MQ for z/OS include:
- The operations and control panels
- The IBM MQ utility program, CSQUTIL
- The dead letter queue handler utility, CSQUDLQH

Applications that use IBM MQ classes for Java, IBM MQ classes for JMS, IBM MQ classes for .NET, or the Message Service Clients for C/C++ and .NET use the MQI indirectly.

MCAs also issue MQI calls and the user IDs associated with the MCAs need authority to access these IBM MQ objects. For more information about these user IDs and the authorities they require, see "Channel authorization" on page 485.

On z/OS, applications can also use MQSC commands to access these IBM MQ objects but command security and command resource security provide the authority checks in these circumstances.
z/OS For more information, see "Command security and command resource security" on page 450 and "MQSC commands and the system command input queue" on page 451.

On IBM i, a user that issues a CL command in Group 2 might require authority to access an IBM MQ object associated with the command. For more information, see "When authority checks are performed" on page 453.

When authority checks are performed:

Authority checks are performed when an application attempts to access a queue manager, queue, process, or namelist.

On IBM i, authority checks might also be performed when a user issues a CL command in Group 2 that accesses any of these IBM MQ objects. The checks are performed in the following circumstances:

When an application connects to a queue manager using an MQCONN or MQCONNX call

The queue manager asks the operating system for the user ID associated with the application. The queue manager then checks that the user ID is authorized to connect to it and retains the user ID for future checks.

Users do not have to sign on to IBM MQ. IBM MQ assumes that users are signed on to the underlying operating system and are been authenticated by it.

When an application opens an IBM MQ object using an MQOPEN or MQPUT1 call

All authority checks are performed when an object is opened, not when it is accessed later. For example, authority checks are performed when an application opens a queue. They are not performed when the application puts messages on the queue or gets messages from the queue.

When an application opens an object, it specifies the types of operation it needs to perform on the object. For example, an application might open a queue to browse the messages on it, get messages from it, but not to put messages on it. For each type of operation, the queue manager checks that the user ID associated with the application has the authority to perform that operation.

When an application opens a queue, the authority checks are performed against the object named in the `ObjectName` field of the object descriptor. The `ObjectName` field is used on the MQOPEN or MQPUT1 calls. If the object is an alias queue or a remote queue definition, the authority checks are performed against the object itself. They are not performed on the queue to which the alias queue or the remote queue definition resolves. This means that the user does not need permission to access it. Limit the authority to create queues to privileged users. If you do not, users might bypass the normal access control simply by creating an alias.

An application can reference a remote queue explicitly. It sets the `ObjectName` and `ObjectQMgrName` fields in the object descriptor to the names of the remote queue and the remote queue manager. The authority checks are performed against the transmission queue with the same name as the remote queue manager. On z/OS, a check is made on the RACF queue profile that matches the remote queue manager name. On platforms other than z/OS, a check is made against the RQMNAME profile that matches the remote queue manager name, if clustering is being used. An application can reference a cluster queue explicitly by setting the `ObjectName` field in the object descriptor to the name of the cluster queue. The authority checks are performed against the cluster transmission queue, `SYSTEM.CLUSTER.TRANSMIT.QUEUE`.

The authority to a dynamic queue is based on the model queue from which it is derived, but is not necessarily the same; see note 1.

The user ID that the queue manager uses for the authority checks is obtained from the operating system. The user ID is obtained when the application connects to the queue manager. A suitably authorized application can issue an MQOPEN call specifying an alternative user ID; access control checks are then made on the alternative user ID. Using an alternate user ID does not change the user ID associated with the application, only the one used for access control checks.

When an application subscribes to a topic using an MQSUB call

When an application subscribes to a topic, it specifies the type of operation that it needs to perform. It is either creating a subscription, altering an existing subscription, or resuming an existing subscription without changing it. For each type of operation, the queue manager checks that the user ID that is associated with the application has the authority to perform the operation.

When an application subscribes to a topic, the authority checks are performed against topic objects that are found in the topic tree. The topic objects are at, or above, the point in the topic tree at which the application subscribed. The authority checks might involve checks on more than one topic object. The user ID that the queue manager uses for the authority checks is obtained from the operating system. The user ID is obtained when the application connects to the queue manager.

The queue manager performs authority checks on subscriber queues but not on managed queues.

When an application deletes a permanent dynamic queue using an MQCLOSE call

The object handle specified on the MQCLOSE call is not necessarily the same one returned by the MQOPEN call that created the permanent dynamic queue. If it is different, the queue manager checks the user ID associated with the application that issued the MQCLOSE call. It checks that the user ID is authorized to delete the queue.

When an application that closes a subscription to remove it did not create it, the appropriate authority is required to remove it.

When a PCF command that operates on an IBM MQ object is processed by the command server

This rule includes the case where a PCF command operates on an authentication information object.

The user ID that is used for the authority checks is the one found in the `UserIdentifier` field in the message descriptor of the PCF command. This user ID must have the required authorities on the queue manager where the command is processed. The equivalent MQSC command encapsulated within an Escape PCF command is treated in the same way. For more information about the `UserIdentifier` field, and how it is set, see "Message context" on page 455.

IBM i **On IBM i, when a user issues a CL command in Group 2 that operates on an IBM MQ object**

This rule includes the case where a CL command in Group 2 operates on an authentication information object.

Checks are performed to determine whether the user has the authority to operate on an IBM MQ object associated with the command. The checks are performed unless the user is a member of the QMQMADM group or has `*ALLOBJ` authority. The authority required depends on the type of operation that the command performs on the object. For example, the command **`CHGMQMQ`**, Change MQM Queue, requires the authority to change the attributes of the queue specified by the command. In contrast, the command **`DSPMQMQ`**, Display MQM Queue, requires the authority to display the attributes of the queue specified by the command.

Many commands operate on more than one object. For example, to issue the command **`DLTMQMQ`**, Delete MQM Queue, the following authorities are required:

- The authority to connect to the queue manager specified by the command
- The authority to delete the queue specified by the command

Some commands operate on no object at all. In this case, the user requires only IBM i authority to issue one of these commands. **`STRMQMLSR`**, Start MQM Listener, is an example of such a command.

Alternate user authority:

When an application opens an object or subscribes to a topic, the application can supply a user ID on the MQOPEN, MQPUT1, or MQSUB call. It can ask the queue manager to use this user ID for authority checks instead of the one associated with the application.

The application succeeds in opening the object only if both the following conditions are met:
- The user ID associated with the application has the authority to supply a different user ID for authority checks. The application is said to have *alternate user authority*.
- The user ID supplied by the application has the authority to open the object for the types of operation requested, or to subscribe to the topic.

Message context:

Message context information allows the application that retrieves a message to find out about the originator of the message. The information is held in fields in the message descriptor and the fields are divided into three logical parts

These parts are as follows:

identity context
These fields contain information about the user of the application that put the message on the queue.

origin context
These fields contain information about the application itself and when the message was put on the queue.

user context
These fields contain message properties that applications can use to select messages that the queue manager should deliver.

When an application puts a message on a queue, the application can ask the queue manager to generate the context information in the message. This is the default action. Alternatively, it can specify that the context fields are to contain no information. The user ID associated with an application requires no special authority to do either of these.

An application can set the identity context fields in a message, allowing the queue manager to generate the origin context, or it can set all the context fields. An application can also pass the identity context fields from a message it has retrieved to a message it is putting on a queue, or it can pass all the context fields. However, the user ID associated with an application requires authority to set or pass context information. An application specifies that it intends to set or pass context information when it opens the queue on which it is about to put messages, and its authority is checked at this time.

Here is a brief description of each of the context fields:

Identity context

UserIdentifier
The user ID associated with the application that put the message. If the queue manager sets this field, it is set to the user ID obtained from the operating system when the application connects to the queue manager.

AccountingToken
Information that can be used to charge for the work done as a result of the message.

ApplIdentityData
If the user ID associated with an application has authority to set the identity context

fields, or to set all the context fields, the application can set this field to any value related to identity. If the queue manager sets this field, it is set to blank.

Origin context

PutApplType
The type of the application that put the message; a CICS transaction, for example.

PutApplName
The name of the application that put the message.

PutDate
The date when the message was put.

PutTime
The time when the message was put.

ApplOriginData
If the user ID associated with an application has authority to set all the context fields, the application can set this field to any value related to origin. If the queue manager sets this field, it is set to blank.

User context

The following values are supported for **MQINQMP** or **MQSETMP**:

MQPD_USER _CONTEXT

The property is associated with the user context.

No special authorization is required to be able to set a property associated with the user context using the MQSETMP call.

On a V7.0 or subsequent queue manager, a property associated with the user context is saved as described for MQOO_SAVE_ALL_CONTEXT. An MQPUT with MQOO_PASS_ALL_CONTEXT specified causes the property to be copied from the saved context into the new message.

MQPD_NO_CONTEXT

The property is not associated with a message context.

An unrecognized value is rejected with MQRC_PD_ERROR. The initial value of this field is **MQPD_NO_CONTEXT**.

For a detailed description of each of the context fields, see MQMD - Message descriptor. For more information about how to use message context, see Message context.

Authority to work with IBM MQ objects on : IBM i IBM i ,UNIXLinuxWindows

The authorization service component provided with IBM MQ is called the *object authority manager (OAM)*. It provides access control via authentication and authorization checks.

- Authentication.

  The authentication check performed by the OAM provided with IBM MQ is basic, and is only performed in specific circumstances. It is not intended to meet the strict requirements expected in a highly secure environment.

  The OAM performs its authentication check when an application connects to a queue manager, and the following conditions are true.

  If an MQCSP structure has been supplied by the connecting application, and the *AuthenticationType* attribute in the MQCSP structure is given the value MQCSP_AUTH_USER_ID_AND_PWD, then the check is performed by the OAM in its MQZID_AUTHENTICATE_USER function. This is the check: the user ID in the MQCSP structure is compared against the user ID in the `IdentityContext` (MQZIC), to determine whether they match. If they do not match, the check fails.

  This basic check is not intended to be a full authentication of the user. For example, there is no check of the authenticity of the user by checking the password supplied in the MQCSP structure. Also, if the application omits an MQCSP structure, then no check is performed.

  If fuller authentication services are required in the queue manager via the authorization service component, then the OAM provided with IBM MQ does not offer this. You must write a new authorization service component, or obtain one from a vendor.
- Authorization.

  The authorization checks are comprehensive, and are intended to meet most normal requirements.

  Authorization checks are performed when an application issues an MQI call to access a queue manager, queue, process, topic, or namelist. They are also performed at other times, for example, when a command is being performed by the Command Server.

On IBM i IBM i , UNIX, Linux and Windows systems, the *authorization service* provides the access control when an application issues an MQI call to access an IBM MQ object that is a queue manager, queue, process, topic, or namelist. This includes checks for alternative user authority and the authority to set or pass context information.

On Windows , the OAM gives members of the Administrators group the authority to access all IBM MQ objects, even when UAC is enabled.

Additionally, on Windows systems, the SYSTEM account has full access to IBM MQ resources.

The authorization service also provides authority checks when a PCF command operates on one of these IBM MQ objects or an authentication information object. The equivalent MQSC command encapsulated within an Escape PCF command is treated in the same way.

IBM i On IBM i , unless the user is a member of the QMQMADM group or has *ALLOBJ authority, the authorization service also provides authority checks when a user issues a CL command in Group 2 that operates on any of these IBM MQ objects or an authentication information object.

The authorization service is an *installable service*, which means that it is implemented by one or more *installable service components*. Each component is invoked using a documented interface. This enables users and vendors to provide components to augment or replace those provided by the IBM MQ products.

The authorization service component provided with IBM MQ is called the *object authority manager (OAM)*. The OAM is automatically enabled for each queue manager you create.

The OAM maintains an access control list (ACL) for each IBM MQ object it is controlling access to. On UNIX and Linux systems, only group IDs can appear in an ACL. This means that all members of a group have the same authorities. On IBM i IBM i and on Windows systems, both user IDs and group IDs can appear in an ACL. This means that authorities can be granted to individual users and groups.

A 12 character limitation applies to both the group and the user ID. UNIX platforms generally restrict the length of a user ID to 12 characters. AIX and Linux have raised this limit but IBM MQ continues to observe a 12 character restriction on all UNIX platforms. If you use a user ID of greater than 12 characters, IBM MQ replaces it with the value "UNKNOWN". Do not define a user ID with a value of "UNKNOWN".

The OAM can authenticate a user and change appropriate identity context fields. You enable this by specifying a connection security parameters structure (MQCSP) on an MQCONNX call. The structure is passed to the OAM Authenticate User function (MQZ_AUTHENTICATE_USER), which sets appropriate identity context fields. If an MQCONNX connection from an IBM MQ client, the information in the MQCSP is flowed to the queue manager to which the client is connecting over the client-connection and server-connection channel. If security exits are defined on that channel, the MQCSP is passed into each security exit and can be altered by the exit. Security exits can also create the MQCSP. For more details of the use of security exits in this context, see Channel security exit programs.

Warning: In some cases, the password in an MQCSP structure for a client application will be sent across a network in plain text. To ensure that client application passwords are protected appropriately, see IBM MQCSP password protection.

On UNIX, Linux and Windows systems, the control command **setmqaut** grants and revokes authorities and is used to maintain the ACLs. For example, the command:

```
setmqaut -m JUPITER -t queue -n MOON.EUROPA -g VOYAGER +browse +get
```

allows the members of the group VOYAGER to browse messages on the queue MOON.EUROPA that is owned by the queue manager JUPITER. It allows the members to get messages from the queue as well. To revoke these authorities later, enter the following command:

```
setmqaut -m JUPITER -t queue -n MOON.EUROPA -g VOYAGER -browse -get
```

The command:

```
setmqaut -m JUPITER -t queue -n MOON.* -g VOYAGER +put
```

allows the members of the group VOYAGER to put messages on any queue with a name that commences with the characters `MOON.`. MOON.* is the name of a generic profile. A *generic profile* allows you to grant authorities for a set of objects using a single **setmqaut** command.

The control command **dspmqaut** is available to display the current authorities that a user or group has for a specified object. The control command **dmpmqaut** is also available to display the current authorities associated with generic profiles.

IBM i On IBM i, an administrator uses the CL command GRTMQMAUT to grant authorities and the CL command RVKMQMAUT to revoke authorities. Generic profiles can be used as well. For example, the CL command:

```
GRTMQMAUT MQMNAME(JUPITER) OBJTYPE(*Q) OBJ('MOON.*') USER(VOYAGER) AUT(*PUT)
```

provides the same function as the previous example of a **setmqaut** command; it allows the members of the group VOYAGER to put messages on any queue with a name that commences with the characters `MOON.`

IBM i The CL command DSPMQMAUT displays the current authorities that user or group has for a specified object. The CL commands WRKMQMAUT and WRKMQMAUTD are also available to work with the current authorities associated with objects and generic profiles.

If you do not want any authority checks, for example, in a test environment, you can disable the OAM.

Using PCF to access OAM commands

On IBM i IBM i, UNIX, Linux and Windows systems, you can use PCF commands to access OAM administration commands.

The PCF commands and their equivalent OAM commands are as follows:

Table 21. PCF commands and their equivalent OAM commands

PCF command	OAM command
Inquire Authority Records	dmpmqaut
Inquire Entity Authority	dspmqaut
Set Authority Record	setmqaut
Delete Authority Record	setmqaut with -remove option

The **`setmqaut`** and **`dmpmqaut`** commands are restricted to members of the mqm group. The equivalent PCF commands can be executed by users in any group who have been granted dsp and chg authorities on the queue manager.

For more information about using these commands, see Introduction to Programmable Command Formats.

Authority to work with IBM MQ objects on z/OS

On z/OS, there are seven categories of authority check associated with calls to the MQI. You must define certain RACF profiles and give appropriate access to these profiles. Use the *RESLEVEL* profile to control how many users IDs are checked.

The seven categories of authority check associated with calls to the MQI:

Connection security
The authority checks that are performed when an application connects to a queue manager

Queue security
The authority checks that are performed when an application opens a queue or deletes a permanent dynamic queue

Process security
The authority checks that are performed when an application opens a process object

Namelist security
The authority checks that are performed when an application opens a namelist object

Alternate user security
The authority checks that are performed when an application requests alternate user authority when opening an object

Context security
The authority checks that are performed when an application opens a queue and specifies that it intends to set or pass the context information in the messages it puts on the queue

Topic security
The authority checks that are performed when an application opens a topic

Each category of authority check is implemented in the same way that command security and command resource security are implemented. You must define certain RACF profiles and give the necessary groups and user IDs access to these profiles at the required levels. For queue security, the level of access determines the types of operation the application can perform on a queue. For context security, the level of access determines whether the application can:

- Pass all the context fields
- Pass all the context fields and set the identity context fields
- Pass and set all the context fields

Each category of authority check can be turned on or off by defining switch profiles.

All the categories, except connection security, are known collectively as *API-resource security*.

By default, when an API-resource security check is performed as a result of an MQI call from an application using a batch connection, only one user ID is checked. When a check is performed as a result of an MQI call from a CICS or IMS application, or from the channel initiator, two user IDs are checked.

By defining a *RESLEVEL profile*, however, you can control whether zero, one, or two users IDs are checked. The number of user IDs that are checked is determined by the user ID associated with the type of connection when an application connects to the queue manager and the access level that user ID has to the RESLEVEL profile. The user ID associated with each type of connection is:

- The user ID of the connecting task for batch connections
- The CICS address space user ID for CICS connections

- The IMS region address space user ID for IMS connections
- The channel initiator address space user ID for channel initiator connections

For more information about the authority to work with IBM MQ objects on z/OS, see “Authority to administer IBM MQ on z/OS” on page 450.

Security for remote messaging

This section deals with remote messaging aspects of security.

You must provide users with authority to use the IBM MQ facilities. This is organized according to actions to be taken with respect to objects and definitions. For example:

- Queue managers can be started and stopped by authorized users
- Applications must connect to the queue manager and have authority to use queues
- Message channels must be created and controlled by authorized users
- Objects are kept in libraries and access to these libraries can be restricted

The message channel agent at a remote site must check that the message being delivered originated from a user with authority to do so at this remote site. In addition, as MCAs can be started remotely, it might be necessary to verify that the remote processes trying to start your MCAs are authorized to do so. There are four possible ways for you to deal with this:

1. Make appropriate use of the PutAuthority attribute of your RCVR, RQSTR, or CLUSRCVR channel definition to control which user is used for authorization checks at the time incoming messages are put to your queues. See the DEFINE CHANNEL command description in the MQSC Command Reference.
2. Implement channel authentication records to reject unwanted connection attempts, or to set an MCAUSER value based on the following: the remote IP address, the remote user ID, the SSL or TLS Subject Distinguished Name (DN) provided, or the remote queue manager name.
3. Implement *user exit* security checking to ensure that the corresponding message channel is authorized. The security of the installation hosting the corresponding channel ensures that all users are properly authorized, so that you do not need to check individual messages.
4. Implement *user exit* message processing to ensure that individual messages are vetted for authorization.

Security of IBM MQ for IBM i objects

This section deals with remote messaging aspects of security.

You must provide users with authority to make use of the IBM MQ for IBM i facilities. This authority is organized according to actions to be taken with respect to objects and definitions. For example:

- Queue managers can be started and stopped by authorized users
- Applications need to connect to the queue manager, and have authority to make use of queues
- Message channels need to be created and controlled by authorized users

The message channel agent at a remote site must check that the message being delivered has derived from a user with authority to isue the message at this remote site. In addition, as MCAs can be started remotely, it might be necessary to verify that the remote processes trying to start your MCAs are authorized to do so. There are four possible ways for you to deal with this:

- Decree in the channel definition that messages must contain acceptable *context* authority, otherwise they are discarded.
- Implement channel authentication records to reject unwanted connection attempts, or to set an MCAUSER value based on one of the following: the remote IP address, the remote user ID, the SSL or TLS Distinguished Name (DN) provided, or the remote queue manager name.

- Implement user exit security checking to ensure that the corresponding message channel is authorized. The security of the installation hosting the corresponding channel ensures that all users are properly authorized, so that you do not need to check individual messages.
- Implement user exit message processing to ensure that individual messages are vetted for authorization.

Here are some facts about the way IBM MQ for IBM i operates security:
- Users are identified and authenticated by IBM i.
- Queue manager services invoked by applications are run with the authority of the queue manager user profile, but in the user's process.
- Queue manager services invoked by user commands are run with the authority of the queue manager user profile.

Security of objects on UNIX and Linux systems

Administration users must be part of the mqm group on your system (including root) if this ID is going to use IBM MQ administration commands.

You should always run amqcrsta as the "mqm" user ID.

User IDs on UNIX and Linux systems

The queue manager converts all uppercase or mixed case user identifiers into lowercase. The queue manager then inserts the user identifiers into the context part of a message, or checks their authorization. Authorizations are therefore based only on lowercase identifiers.

Security of objects on Windows systems

Administration users must be part of both the mqm group and the administrators group on Windows systems if this ID is going to use IBM MQ administration commands.

User IDs on Windows systems

On Windows systems, *if there is no message exit installed*, the queue manager converts any uppercase or mixed case user identifiers into lowercase. The queue manager then inserts the user identifiers into the context part of a message, or checks their authorization. Authorizations are therefore based only on lowercase identifiers.

User IDs across systems

Platforms other than Windows, UNIX and Linux systems use uppercase characters for user IDs in messages.

To allow Windows, UNIX and Linux systems to use lowercase user IDs in messages, the following conversions are carried out by the message channel agent (MCA) on these platforms:

At the sending end
The alphabetic characters in all user IDs are converted to uppercase characters, if there is no message exit installed.

At the receiving end
The alphabetic characters in all user IDs are converted to lowercase characters, if there is no message exit installed.

The automatic conversions are not carried out if you provide a message exit on UNIX, Linux and Windows systems for any other reason.

Using a custom authorization service

IBM MQ supplies an installable authorization service. You can choose to install an alternative service.

The authorization service component supplied with IBM MQ is called the Object Authority Manager (OAM). If the OAM does not supply the authorization facilities you need, you can write your own authorization service component. The installable service functions that must be implemented by an authorization service component are described at Installable services interface reference information.

Access control for clients

Access control is based on user IDs. There can be many user IDs to administer, and user IDs can be in different formats. You can set the server-connection channel property MCAUSER to a special user ID value for use by clients.

Access control in IBM MQ is based on user IDs. The user ID of the process making MQI calls is normally used. For MQ MQI clients, the server-connection MCA makes MQI calls on behalf of MQ MQI clients. You can select an alternative user ID for the server-connection MCA to use for making MQI calls. The alternative user ID can be associated either with the client workstation, or with anything you choose to organize and control the access of clients. The user ID needs to have the necessary authorities allocated to it on the server to issue MQI calls. Choosing an alternative user ID is preferable to allowing clients to make MQI calls with the authority of the server-connection MCA.

Table 22. The user ID used by a server-connection channel

User ID	**When used**
The user ID that is set by a security exit	Used unless blocked by a `CHLAUTH TYPE(BLOCKUSER)` rule. See the following section, "Setting the user ID in a security exit" on page 468 for more information.
The user ID that is set by a CHLAUTH rule	Used unless over-ridden by a security exit. See Channel Authentication Records for more information.
The user ID that is defined in the `MCAUSER` attribute in the SVRCONN channel definition	Used unless over-ridden by a security exit or a CHLAUTH rule.
The user ID that is flowed from the client machine	Used when no user ID is set by any other means.
The user ID that started the server-connection channel	Used when no user ID is set by any other means and no client user ID is flowed. See the following section, "The user ID that runs the channel program" on page 468 for more information.

Because the server-connection MCA makes MQI calls on behalf of remote users, it is important to consider the security implications of the server-connection MCA issuing MQI calls on behalf of remote clients and how to administer the access of a potentially large number of users.

- One approach is for the server-connection MCA to issue MQI calls on its own authority. But beware, it is normally undesirable for the server-connection MCA, with its powerful access capabilities, to issue MQI calls on behalf of client users.
- Another approach is to use the user ID that flows from the client. The server-connection MCA can issue MQI calls using the access capabilities of the client user ID. This approach presents a number of questions to consider:
  1. There are different formats for the user ID on different platforms. This sometimes causes problems if the format of the user ID on the client differs from the acceptable formats on the server.
  2. There are potentially many clients, with different, and changing user IDs. The IDs need to be defined and managed on the server.
  3. Is the user ID to be trusted? Any user ID can be flowed from a client, not necessarily the ID of the logged on user. For example, the client might flow an ID with full `mqm` authority that was intentionally only defined on the server for security reasons.
- The preferred approach is to define client identification tokens at the server, and so limit the capabilities of client connected applications. This is typically done by setting the server-connection channel property MCAUSER to a special user ID value to be used by clients, and defining few IDs for use by clients with different level of authorization on the server.

Setting the user ID in a security exit

For IBM MQ MQI clients, the process that issues the MQI calls is the server-connection MCA. The user ID used by the server-connection MCA is contained in either the `MCAUserIdentifier` or `LongMCAUserIdentifier` fields of the MQCD. The contents of these fields are set by:

- Any values set by security exits
- The user ID from the client
- MCAUSER (in the server-connection channel definition)

The security exit can override the values that are visible to it, when it is invoked.

- If the server-connection channel MCAUSER attribute is set to nonblank, the MCAUSER value is used.
- If the server-connection channel MCAUSER attribute is blank, the user ID received from the client is used.
- If the server-connection channel MCAUSER attribute is blank, and no user ID is received from the client then the user ID that started the server-connection channel is used.

The IBM MQ client does not flow the asserted user ID to the server when a client-side security exit is in use.

The user ID that runs the channel program

When the user ID fields are derived from the user ID that started the server-connection channel, the following value is used:

- For z/OS, the user ID assigned to the channel initiator started task by the z/OS started procedures table.
- For TCP/IP (non- z/OS), the user ID from the `inetd.conf` entry, or the user ID that started the listener.
- For SNA (non- z/OS), the user ID from the SNA Server entry or (if there is none) the incoming attach request, or the user ID that started the listener.
- For NetBIOS or SPX, the user ID that started the listener.

If any server-connection channel definitions exist that have the MCAUSER attribute set to blank, clients can use this channel definition to connect to the queue manager with access authority determined by the user ID supplied by the client. This might be a security exposure if the system on which the queue manager is running allows unauthorized network connections. The IBM MQ default server-connection channel (SYSTEM.DEF.SVRCONN) has the MCAUSER attribute set to blank. To prevent unauthorized access, update the MCAUSER attribute of the default definition with a user ID that has no access to IBM MQ MQ objects.

Case of user IDs

When you define a channel with `runmqsc`, the MCAUSER attribute is changed to uppercase unless the user ID is contained within single quotation marks.

For servers on UNIX, Linux and Windows systems, the content of the `MCAUserIdentifier` field that is received from the client is changed to lowercase.

For servers on IBM i, the content of the `LongMCAUserIdentifier` field that is received from the client is changed to uppercase.

For servers on UNIX and Linux systems, the content of the `LongMCAUserIdentifier` field that is received from the client is changed to lowercase.

By default, the user ID that is passed when a MQ JMS binding application is used, is the user ID for the JVM the application is running on.

It is also possible to pass a user ID via the `createQueueConnection` method.

Planning confidentiality

Plan how to keep your data confidential.

You can implement confidentiality at the application level or at link level. You might choose to use SSL or TLS, in which case you must plan your usage of digital certificates. You can also use channel exit programs if standard facilities do not satisfy your requirements.

Related concepts:

"Comparing link level security and application level security"
This topic contains information about various aspects of link level security and application level security, and compares the two levels of security.

"Channel exit programs" on page 476
Channel exit programs are programs that are called at defined places in the processing sequence of an MCA. Users and vendors can write their own channel exit programs. Some are supplied by IBM.

"Protecting channels with SSL and TLS" on page 487
SSL and TLS support in IBM MQ uses the queue manager authentication information object, and various MQSC commands. You must also consider your use of digital certificates.

Comparing link level security and application level security

This topic contains information about various aspects of link level security and application level security, and compares the two levels of security.

Link level and application level security are illustrated in Figure 63.

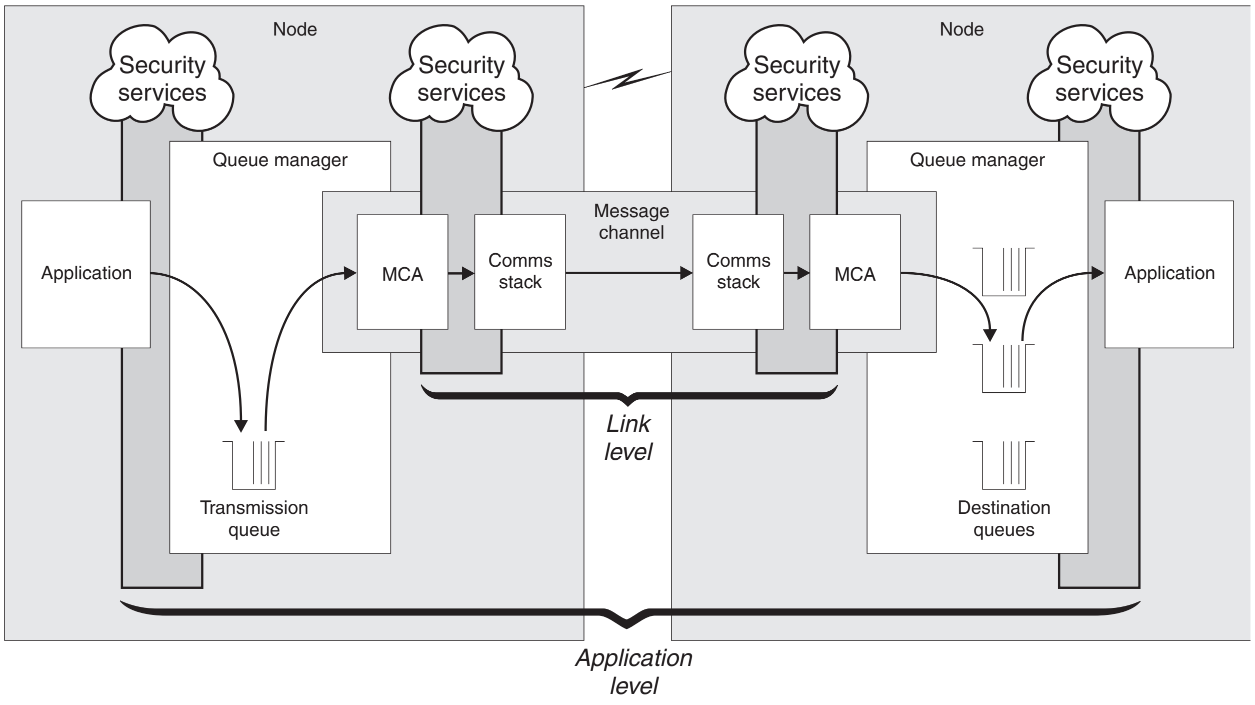

Figure 63. Link level security and application level security

Protecting messages in queues

Link level security can protect messages while they are transferred from one queue manager to another. It is particularly important when messages are transmitted over an insecure network. It cannot, however, protect messages while they are stored in queues at either a source queue manager, a destination queue manager, or an intermediate queue manager.

Application level security, by comparison, can protect messages while they are stored in queues and applies even when distributed queuing is not used. This is the major difference between link level security and application level security and is illustrated in Figure 63 on page 471.

Queue managers not running in controlled and trusted environments

If a queue manager is running in a controlled and trusted environment, the access control mechanisms provided by IBM MQ might be considered sufficient to protect the messages stored on its queues. This is particularly true if only local queuing is involved and messages never leave the queue manager. Application level security in this case might be considered unnecessary.

Application level security might also be considered unnecessary if messages are transferred to another queue manager that is also running in a controlled and trusted environment, or are received from such a queue manager. The need for application level security becomes greater when messages are transferred to, or received from, a queue manager that is not running in a controlled and trusted environment.

Differences in cost

Application level security might cost more than link level security in terms of administration and performance.

The cost of administration is likely to be greater because there are potentially more constraints to configure and maintain. For example, you might need to ensure that a particular user sends only certain types of message and sends messages only to certain destinations. Conversely, you might need to ensure that a particular user receives only certain types of message and receives messages only from certain sources. Instead of managing the link level security services on a single message channel, you might need to be configuring and maintaining rules for every pair of users who exchange messages across that channel.

There might be an effect on performance if security services are invoked every time an application puts or gets a message.

Organizations tend to consider link level security first because it might be easier to implement. They consider application level security if they discover that link level security does not satisfy all their requirements.

Availability of components

Generally, in a distributed environment, a security service requires a component on at least two systems. For example, a message might be encrypted on one system and decrypted on another. This applies to both link level security and application level security.

In a heterogeneous environment, with different platforms in use, each with different levels of security function, the required components of a security service might not be available for every platform on which they are needed and in a form that is easy to use. This is probably more of an issue for application level security than for link level security, particularly if you intend to provide your own application level security by buying in components from various sources.

Messages in a dead letter queue

If a message is protected by application level security, there might be a problem if, for any reason, the message does not reach its destination and is put on a dead letter queue. If you cannot work out how to process the message from the information in the message descriptor and the dead letter header, you might need to inspect the contents of the application data. You cannot do this if the application data is encrypted and only the intended recipient can decrypt it.

What application level security cannot do

Application level security is not a complete solution. Even if you implement application level security, you might still require some link level security services. For example:

- When a channel starts, the mutual authentication of the two MCAs might still be a requirement. This can be done only by a link level security service.
- Application level security cannot protect the transmission queue header, MQXQH, which includes the embedded message descriptor. Nor can it protect the data in IBM MQ channel protocol flows other than message data. Only link level security can provide this protection.
- If application level security services are invoked at the server end of an MQI channel, the services cannot protect the parameters of MQI calls that are sent over the channel. In particular, the application data in an MQPUT, MQPUT1, or MQGET call is unprotected. Only link level security can provide the protection in this case.

Link level security

Link level security refers to those security services that are invoked, directly or indirectly, by an MCA, the communications subsystem, or a combination of the two working together.

Link level security is illustrated in Figure 63 on page 471.

Here are some examples of link level security services:

- The MCA at each end of a message channel can authenticate its partner. This is done when the channel starts and a communications connection has been established, but before any messages start to flow. If authentication fails at either end, the channel is closed and no messages are transferred. This is an example of an identification and authentication service.
- A message can be encrypted at the sending end of a channel and decrypted at the receiving end. This is an example of a confidentiality service.
- A message can be checked at the receiving end of a channel to determine whether its contents have been deliberately modified while it was being transmitted over the network. This is an example of a data integrity service.

Link level security provided by IBM MQ

The primary means of provision of confidentiality and data integrity in IBM MQ is by the use of SSL or TLS. For more information about the use of SSL and TLS in IBM MQ, see “SSL and TLS security protocols in IBM MQ” on page 397. For authentication, IBM MQ provides the facility to use channel authentication records. Channel authentication records offer precise control over the access granted to connecting systems, at the level of individual channels or groups of channels. For more information, see “Channel authentication records” on page 424.

Providing your own link level security

This collection of topics describes how you can provide your own link level security services. Writing your own channel exit programs is the main way to provide your own link level security services.

Channel exit programs are introduced in "Channel exit programs" on page 476. The same topic also describes the channel exit program that is supplied with IBM MQ for Windows (the SSPI channel exit program). This channel exit program is supplied in source format so that you can modify the source code to suit your requirements. If this channel exit program, or channel exit programs available from other vendors, do not meet your requirements, you can design and write your own. This topic suggests ways in which channel exit programs can provide security services. For information about how to write a channel exit program, see Writing channel-exit programs.

Link level security using a security exit:

Security exits normally work in pairs; one at each end of a channel. They are called immediately after the initial data negotiation has completed on channel startup.

Security exits can be used to provide identification and authentication, access control, and confidentiality.

Link level security using a message exit:

A message exit can be used only on a message channel, not on an MQI channel. It has access to both the transmission queue header, MQXQH, which includes the embedded message descriptor, and the application data in a message. It can modify the contents of the message and change its length.

A message exit can be used for any purpose that requires access to the whole message rather than a portion of it.

Message exits can be used to provide identification and authentication, access control, confidentiality, data integrity, and non-repudiation, and for reasons other than security.

Link level security using send and receive exits:

Send and receive exits can be used on both message and MQI channels. They are called for all types of data that flow on a channel, and for flows in both directions.

Send and receive exits have access to each transmission segment. They can modify its contents and change its length.

On a message channel, if an MCA needs to split a message and send it in more than one transmission segment, a send exit is called for each transmission segment containing a portion of the message and, at the receiving end, a receive exit is called for each transmission segment. The same occurs on an MQI channel if the input or output parameters of an MQI call are too large to be sent in a single transmission segment.

On an MQI channel, byte 10 of a transmission segment identifies the MQI call, and indicates whether the transmission segment contains the input or output parameters of the call. Send and receive exits can examine this byte to determine whether the MQI call contains application data that might need to be protected.

When a send exit is called for the first time, to acquire and initialize any resources it needs, it can ask the MCA to reserve a specified amount of space in the buffer that holds a transmission segment. When it is called later to process a transmission segment, it can use this space to add an encrypted key or a digital signature, for example. The corresponding receive exit at the other end of the channel can remove the data added by the send exit, and use it to process the transmission segment.

Send and receive exits are best suited for purposes in which they do not need to understand the structure of the data they are handling and can therefore treat each transmission segment as a binary object.

Send and receive exits can be used to provide confidentiality and data integrity, and for uses other than security.

Related information:

Identifying the API call in a send or receive exit program

Application level security

Application level security refers to those security services that are invoked at the interface between an application and a queue manager to which it is connected.

These services are invoked when the application issues MQI calls to the queue manager. The services might be invoked, directly or indirectly, by the application, the queue manager, another product that supports IBM MQ, or a combination of any of these working together. Application level security is illustrated in Figure 63 on page 471.

Application level security is also known as *end-to-end security* or *message level security*.

Here are some examples of application level security services:

- When an application puts a message on a queue, the message descriptor contains a user ID associated with the application. However, there is no data present, such as an encrypted password, that can be used to authenticate the user ID. A security service can add this data. When the message is eventually retrieved by the receiving application, another component of the service can authenticate the user ID using the data that has travelled with the message. This is an example of an identification and authentication service.
- A message can be encrypted when it is put on a queue by an application and decrypted when it is retrieved by the receiving application. This is an example of a confidentiality service.
- A message can be checked when it is retrieved by the receiving application. This check determines whether its contents have been deliberately modified since it was first put on a queue by the sending application. This is an example of a data integrity service.

IBM MQ Advanced Message Security

IBM MQ Advanced Message Security (IBM MQ AMS) is a separately licensed component of IBM MQ that provides a high level of protection for sensitive data flowing through the IBM MQ network, while not impacting the end applications.

If you are moving highly sensitive or valuable information, especially confidential or payment-related information such as patient records or credit card details, you must pay special attention to information security. Ensuring that information moving around the enterprise retains its integrity and is protected from unauthorized access is an ongoing challenge and responsibility. You are also likely to be required to comply with security regulations, at the risk of penalties for non-compliance.

You can develop your own security extensions to IBM MQ. However, such solutions require specialist skills and can be complicated and expensive to maintain. IBM MQ Advanced Message Security helps address these challenges when moving information around the enterprise between virtually every type of commercial IT system.

IBM MQ Advanced Message Security extends the security features of IBM MQ in the following ways:

- It provides application-level, end-to-end data protection for your point to point messaging infrastructure, using either encryption or digital signing of messages.
- It provides comprehensive security without writing complex security code or modifying or recompiling existing applications.

- It uses Public Key Infrastructure (PKI) technology to provide authentication, authorization, confidentiality, and data integrity services for messages.
- It provides administration of security policies for mainframe and distributed servers.
- It supports both IBM MQ servers and clients.
- It integrates with IBM MQ Managed File Transfer to provide an end-to-end secure messaging solution.

For more information, see “IBM MQ Advanced Message Security” on page 849.

Providing your own application level security

This collection of topics describes how you can provide your own application level security services.

To help you implement application level security, IBM MQ provides two exits, the API exit and the API-crossing exit.

These exits can provide identification and authentication, access control, confidentiality, data integrity, and non-repudiation services, and other functions not related to security.

If the API exit or API-crossing exit is not supported in your system environment, you might want to consider other ways of providing your own application level security. One way is to develop a higher level API that encapsulates the MQI. Programmers then use this API, instead of the MQI, to write IBM MQ applications.

The most common reasons for using a higher level API are:
- To hide the more advanced features of the MQI from programmers.
- To enforce standards in the use of the MQI.
- To add function to the MQI. This additional function can be security services.

Some vendor products use this technique to provide application level security for IBM MQ.

If you are planning to provide security services in this way, note the following regarding data conversion:
- If a security token, such as a digital signature, has been added to the application data in a message, any code performing data conversion must be aware of the presence of this token.
- A security token might have been derived from a binary image of the application data. Therefore, any checking of the token must be done before converting the data.
- If the application data in a message has been encrypted, it must be decrypted before data conversion.

Channel exit programs

Channel exit programs are programs that are called at defined places in the processing sequence of an MCA. Users and vendors can write their own channel exit programs. Some are supplied by IBM.

There are several types of channel exit program, but only four have a role in providing link level security:
- Security exit
- Message exit
- Send exit
- Receive exit

These four types of channel exit program are illustrated in Figure 64 on page 477 and are described in the following topics.

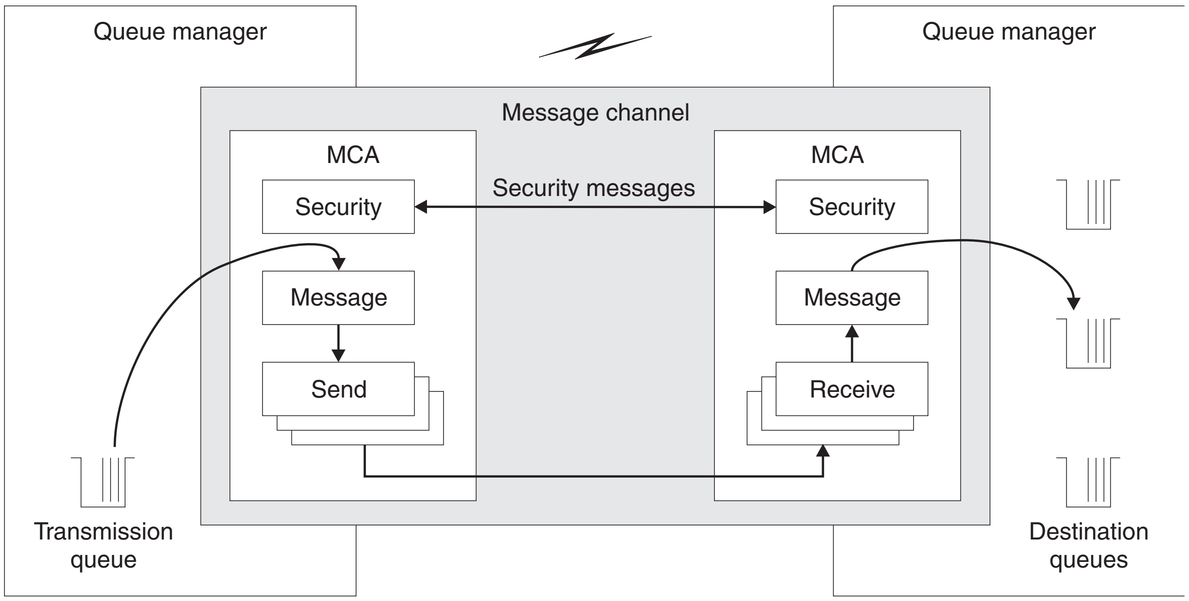

Figure 64. Security, message, send, and receive exits on a message channel

Related information:

Channel-exit programs for messaging channels

Security exit overview

Security exits normally work in pairs. They are called before messages flow and their purpose is to allow an MCA to authenticate its partner.

Security exits normally work in pairs; one at each end of a channel. They are called immediately after the initial data negotiation has completed on channel startup, but before any messages start to flow. The primary purpose of the security exit is to enable the MCA at each end of a channel to authenticate its partner. However, there is nothing to prevent a security exit from performing other function, even function that has nothing to do with security.

Security exits can communicate with each other by sending *security messages*. The format of a security message is not defined and is determined by the user. One possible outcome of the exchange of security messages is that one of the security exits might decide not to proceed any further. In that case, the channel is closed and messages do not flow. If there is a security exit at only one end of a channel, the exit is still called and can elect whether to continue or to close the channel.

Security exits can be called on both message and MQI channels. The name of a security exit is specified as a parameter in the channel definition at each end of a channel.

For more information about security exits, see “Link level security using a security exit” on page 474.

Message exit

Message exits operate only on message channels and normally work in pairs. A message exit can operate on the whole message and make various changes to it.

Message exits at the sending and receiving ends of a channel normally work in pairs. A message exit at the sending end of a channel is called after the MCA has got a message from the transmission queue. At the receiving end of a channel, a message exit is called before the MCA puts a message on its destination queue.

A message exit has access to both the transmission queue header, MQXQH, which includes the embedded message descriptor, and the application data in a message. A message exit can modify the contents of the message and change its length. A change of length might be the result of compressing, decompressing, encrypting, or decrypting the message. It might also be the result of adding data to the message, or removing data from it.

Message exits can be used for any purpose that requires access to the whole message, rather than a portion of it, and not necessarily for security.

A message exit can determine that the message it is currently processing should not proceed any further towards its destination. The MCA then puts the message on the dead letter queue. A message exit can also close the channel.

Message exits can be called only on message channels, not on MQI channels. This is because the purpose of an MQI channel is to enable the input and output parameters of MQI calls to flow between the IBM MQ MQI client application and the queue manager.

The name of a message exit is specified as a parameter in the channel definition at each end of a channel. You can also specify a list of message exits to be run in succession.

For more information about message exits, see “Link level security using a message exit” on page 474.

Send and receive exits

Send and receive exits typically work in pairs. They operate on transmission segments and are best used where the structure of the data they are processing is not relevant.

A *send exit* at one end of a channel and a *receive exit* at the other end normally work in pairs. A send exit is called just before an MCA issues a communications send to send data over a communications connection. A receive exit is called just after an MCA has regained control following a communications receive and has received data from a communications connection. If sharing conversations is in use, over an MQI channel, a different instance of a send and receive exit is called for each conversation.

The IBM MQ channel protocol flows between two MCAs on a message channel contain control information as well as message data. Similarly, on an MQI channel, the flows contain control information as well as the parameters of MQI calls. Send and receive exits are called for all types of data.

Message data flows in only one direction on a message channel but, on an MQI channel, the input parameters of an MQI call flow in one direction and the output parameters flow in the other. On both message and MQI channels, control information flows in both directions. As a result, send and receive exits can be called at both ends of a channel.

The unit of data that is transmitted in a single flow between two MCAs is called a *transmission segment*. Send and receive exits have access to each transmission segment. They can modify its contents and change its length. A send exit, however, must not change the first 8 bytes of a transmission segment. These 8 bytes form part of the IBM MQ channel protocol header. There are also restrictions on how much a send exit can increase the length of a transmission segment. In particular, a send exit cannot increase its length beyond the maximum that was negotiated between the two MCAs at channel startup.

On a message channel, if a message is too large to be sent in a single transmission segment, the sending MCA splits the message and sends it in more than one transmission segment. As a consequence, a send exit is called for each transmission segment containing a portion of the message and, at the receiving end, a receive exit is called for each transmission segment. The receiving MCA reconstitutes the message from the transmission segments after they have been processed by the receive exit.

Similarly, on an MQI channel, the input or output parameters of an MQI call are sent in more than one transmission segment if they are too large. This might occur, for example, on an MQPUT, MQPUT1, or MQGET call if the application data is sufficiently large.

Taking these considerations into account, it is more appropriate to use send and receive exits for purposes in which they do not need to understand the structure of the data they are handling and can therefore treat each transmission segment as a binary object.

A send or a receive exit can close a channel.

The names of a send exit and a receive exit are specified as parameters in the channel definition at each end of a channel. You can also specify a list of send exits to be run in succession. Similarly, you can specify a list of receive exits.

For more information about send and receive exits, see “Link level security using send and receive exits” on page 474.

Planning data integrity

Plan how to preserve the integrity of your data.

You can implement data integrity at the application level or at link level.

At the application level, you can use API exit programs if standard facilities do not satisfy your requirements. You might choose to use IBM MQ Advanced Message Security (AMS) to digitally sign messages in order to protect against unauthorized modification.

At the link level, you might choose to use SSL or TLS, in which case you must plan your usage of digital certificates. You can also use channel exit programs if standard facilities do not satisfy your requirements.

Related concepts:

"Protecting channels with SSL and TLS" on page 487
SSL and TLS support in IBM MQ uses the queue manager authentication information object, and various MQSC commands. You must also consider your use of digital certificates.

"Data integrity in IBM MQ" on page 396
You can use a data integrity service to detect whether a message has been modified.

"IBM MQ Advanced Message Security" on page 475
IBM MQ Advanced Message Security (IBM MQ AMS) is a separately licensed component of IBM MQ that provides a high level of protection for sensitive data flowing through the IBM MQ network, while not impacting the end applications.

Channel-exit calls and data structures

Planning auditing

Decide what data you need to audit, and how you will capture and process audit information. Consider how to check that your system is correctly configured.

There are several aspects to activity monitoring. The aspects you must consider are often defined by auditor requirements, and these requirements are often driven by regulatory standards such as HIPAA (Health Insurance Portability and Accountability Act) or SOX (Sarbanes-Oxley). IBM MQ provides features intended to help with compliance to such standards.

Consider whether you are interested only in exceptions or whether you are interested in all system behavior.

Some aspects of auditing can also be considered as operational monitoring; one distinction for auditing is that you are often looking at historic data, not just looking at real-time alerts. Monitoring is covered in the section Monitoring and performance.

What data to audit

Consider what types of data or activity you need to audit, as described in the following sections:

Changes made to IBM MQ using the IBM MQ interfaces
Configure IBM MQ to issue instrumentation events, specifically command events and configuration events.

Changes made to IBM MQ outside its control
Some changes can affect how IBM MQ behaves, but cannot be directly monitored by IBM MQ. Examples of such changes include changes to the configuration files `mqs.ini`, `qm.ini`, and `mqclient.ini`, the creation and deletion of queue managers, installation of binary files such as user exit programs, and changes to file permissions. To monitor these activities, you must use tools running at the level of the operating system. Different tools are available and appropriate for different operating systems. You might also have logs created by associated tools such as *sudo*.

Operational control of IBM MQ
You might have to use operating system tools to audit activities such as the starting and stopping of queue managers. In some cases, IBM MQ can be configured to issue instrumentation events.

Application activity within IBM MQ
To audit the actions of applications, for example opening of queues and putting and getting of messages, configure IBM MQ to issue appropriate events.

Intruder alerts
To audit attempted breaches of security, configure your system to issue authorization events. Channel events might also be useful to show activity, particularly if a channel ends unexpectedly.

Planning the capture, display, and archiving of audit data

Many of the elements you need are reported as IBM MQ event messages. You must choose tools that can read and format these messages. If you are interested in long-term storage and analysis you must move them to an auxiliary storage mechanism such as a database. If you do not process these messages, they remain on the event queue, possibly filling the queue. You might decide to implement a tool that automatically takes action based on some events; for example, to issue an alert when a security failure happens.

Verifying that your system is correctly configured

A set of tests are supplied with the MQ Explorer. Use these to check your object definitions for problems.

Also, check periodically that the system configuration is as you expect. Although command and configuration events can report when something is changed, it is also useful to dump the configuration and compare it to a known good copy.

Planning security by topology

This section covers security in specific situations, namely for channels, queue manager clusters, publish/subscribe and multicast applications, and when using a firewall.

See the following subtopics for more information:

Channel authorization

When you send or receive a message through a channel, you need to provide access to various IBM MQ resources. Message Channel Agents (MCAs) are essentially IBM MQ applications that move messages between queue managers, and as such require access to various IBM MQ resources to operate correctly.

To receive messages at PUT time for MCAs, you can use either the user ID associated with the MCA, or the user ID associated with the message.

At CONNECT time you can map the asserted user ID to an alternative user, by using **CHLAUTH** channel authentication records.

In IBM MQ, channels can be protected by TLS support.

The user IDs associated with sending and receiving channels, excluding the sender channel where the MCAUSER attribute is unused, require access to the following resources:

- The user ID associated with a sending channel requires access to the queue manager, the transmission queue, the dead-letter queue, and access to any other resources that are required by channel exits.
- The MCAUSER user ID of a receiver channel needs *+setall* authority. The reason is that the receiver channel has to create the full MQMD, including all context fields, using the data it received from the remote sender channel.

  The queue manager therefore requires that the user performing this activity has the *+setall* authority. This *+setall* authority must be granted to the user for:
  - All queues that the receiver channel validly puts messages to.
  - The queue manager object. See Authorizations for context for further information.
- The MCAUSER user ID of a receiver channel where the originator requested a COA report message needs *+passid* authority on the transmission queue that returns the report message. Without this authority, AMQ8077 error messages are logged.
- With the user ID associated with the receiving channel you can open the target queues to put messages onto the queues.

  This involves the Message queuing Interface (MQI), so additional access control checks might need to be made if you are not using the IBM MQ Object Authority Manager (OAM).

  You can specify whether the authorization checks are made against the user ID associated with the MCA (as described in this topic), or against the user ID associated with the message (from the MQMD UserIdentifier field).

  For the channel types to which it applies, the **PUTAUT** parameter of a channel definition specifies which user ID is used for these checks.
  - The channel defaults to using the queue manager's service account, that will have full administrative rights and requires no special authorizations

    In the case of server-connection channels, administrative connections are blocked by default by CHLAUTH rules and require explicit provisioning.

Channels of type receiver, requester, and cluster-receiver allow local administration by any adjacent queue manager, unless the administrator takes steps to restrict this access.

- V 8.0.0.4 Before Version 8.0.0, Fix Pack 4, if you use a user ID that lacks IBM MQ administrative privileges, then you must grant **dsp** and **ctrlx** authority for the channel to that user ID for the channel to work. From Version 8.0.0, Fix Pack 4, it is not necessary to grant *dsp* and *ctrlx* authority for the MCAUSER user ID of a receiver channel.

  Attention: When a channel reset is needed for message batch confirmation, IBM MQ attempts to query the channel, which does require **+dsp** authority.
- The MCAUSER attribute is unused for the SDR channel type.
- If you use the user ID associated with the message, it is likely that the user ID is from a remote system.

  This remote system user ID must be recognized by the target system. For example, issue the following commands:
  -
```
setmqaut -m QMgrName -t qmgr -g GroupName +connect +inq +setall
```
  -
```
setmqaut -m QMgrName -t chl -n Profile -g GroupName +dsp +ctrlx
```
    where *Profile* is a channel.
  -
```
setmqaut -m QMgrName -t q -n Profile -g GroupName +put +setall
```
    where *Profile* is a dead-letter queue, if set.
  -
```
setmqaut -m QMgrName -t q -n Profile -g GroupName +put +setall
```
    where *Profile* is a list of authorized queues.

  Attention: Exercise caution when authorizing a user ID to place messages onto the Command Queue or other sensitive system queues.

The user ID associated with the MCA depends on the type of MCA. There are two types of MCA:

Caller MCA
MCAs that initiate a channel. Caller MCAs can be started as individual processes, as threads of the channel initiator, or as threads of a process pool. The user ID used is the user ID associated with the parent process (the channel initiator), or the user ID associated with the process that starts the MCA.

Responder MCA
Responder MCAs are MCAs that are started as a result of a request by a caller MCA. Responder MCAs can be started as individual processes, as threads of the listener, or as threads of a process pool. The user ID can be any one of the following types (in this order of preference):

1. On APPC, the caller MCA can indicate the user ID to be used for the responder MCA. This is called the network user ID and applies only to channels started as individual processes. Set the network user ID by using the USERID parameter of the channel definition.
2. If the **USERID** parameter is not used, the channel definition of the responder MCA can specify the user ID that the MCA must use. Set the user ID by using the **MCAUSER** parameter of the channel definition.
3. If the user ID has not been set by either of the previous (two) methods, the user ID of the process that starts the MCA or the user ID of the parent process (the listener) is used.

Related concepts:

"Channel authentication records" on page 424
To exercise more precise control over the access granted to connecting systems at a channel level, you can use channel authentication records.

Related information:

Channel authentication record properties

Protecting channel initiator definitions

Only members of the mqm group can manipulate channel initiators.

IBM MQ channel initiators are not IBM MQ objects; access to them is not controlled by the OAM. IBM MQ does not allow users or applications to manipulate these objects, unless their user ID is a member of the mqm group. If you have an application that issues the PCF command **StartChannelInitiator** , the user ID specified in the message descriptor of the PCF message must be a member of the mqm group on the target queue manager.

A user ID must also be a member of the mqm group on the target machine to issue the equivalent MQSC commands through the Escape PCF command or using **runmqsc** in indirect mode.

Transmission queues

Queue managers automatically put remote messages on a transmission queue; no special authority is required for this.

However, if you need to put a message directly on a transmission queue, this requires special authorization; see Table 25 on page 521.

Channel exits

If channel authentication records are not suitable, you can use channel exits for added security. A security exit forms a secure connection between two security exit programs. One program is for the sending message channel agent (MCA), and one is for the receiving MCA.

See "Channel exit programs" on page 476 for more information about channel exits.

Protecting channels with SSL and TLS

SSL and TLS support in IBM MQ uses the queue manager authentication information object, and various MQSC commands. You must also consider your use of digital certificates.

Digital certificates and key repositories

It is good practice to set the queue manager certificate label attribute (`CERTLABL`) to the name of the personal certificate to be used for the majority of channels, and override it for exceptions, by setting the certificate label on those channels that require different certificates.

If you need many channels with certificates that differ from the default certificate set on the queue manager, you should consider dividing the channels between several queue managers or use an MQIPT proxy in front of the queue manager to present a different certificate.

You can use a different certificate for every channel, but if you store too many certificates in a key repository, you might expect performance to be affected when starting SSL/TLS channels. Try to keep the number of certificates in a key repository to less than about 50 and consider 100 to be a maximum as GSKit performance decreases sharply with larger key repositories.

Allowing multiple certificates on the same queue manager increases the chances that multiple CA certificates will be used on the same queue manager. This increases the odds of certificate Subject Distinguished Name namespace clashes for certificates issued by separate certificate authorities.

While professional certificate authorities are likely to be more careful, inhouse certificate authorities often lack clear naming conventions and you could end up with unintended matches between one CA and another.

You should check the certificate Issuer Distinguished Name in addition to the Subject Distinguished Name. To do this, use a channel authentication SSLPEERMAP record and set both the **SSLPEER** and **SSLCERTI** fields to match the Subject DN and Issuer DN respectively.

Self-signed and CA-signed certificates

It is important to plan your use of digital certificates, both when you are developing and testing your application, and for its use in production. You can use CA-signed certificates or self-signed certificates, depending on the usage of your queue managers and client applications.

CA-signed certificates
: For production systems, obtain your certificates from a trusted certificate authority (CA). When you obtain a certificate from an external CA, you pay for the service.

Self-signed certificates
: While you are developing your application you can use self-signed certificates or certificates issued by a local CA, depending on platform:

Windows UNIX Linux On Windows, UNIX, and Linux systems, you can use self-signed certificates. See “Creating a self-signed personal certificate on UNIX, Linux, and Windows systems” on page 681for instructions.

IBM i On IBM i systems, you can use certificates signed by the local CA. See “Requesting a server certificate on IBM i” on page 666 for instructions.

z/OS On z/OS, you can use either self-signed or local CA-signed certificates. See “Creating a self-signed personal certificate on z/OS” on page 706 or “Requesting a personal certificate on z/OS” on page 707 for instructions.

Self-signed certificates are not suitable for production use, for the following reasons:

- Self-signed certificates cannot be revoked, which might allow an attacker to spoof an identity after a private key has been compromised. CAs can revoke a compromised certificate, which prevents its further use. CA-signed certificates are therefore safer to use in a production environment, though self-signed certificates are more convenient for a test system.
- Self-signed certificates never expire. This is both convenient and safe in a test environment, but in a production environment it leaves them open to eventual security breaches. The risk is compounded by the fact that self-signed certificates cannot be revoked.
- A self-signed certificate is used both as a personal certificate and as a root (or trust anchor) CA certificate. A user with a self-signed personal certificate might be able to use it to sign other personal certificates. In general, this is not true of personal certificates issued by a CA, and represents a significant exposure.

CipherSpecs and digital certificates

Only a subset of the supported CipherSpecs can be used with all of the supported types of digital certificate. It is therefore necessary to choose an appropriate CipherSpec for your digital certificates. Similarly, if your organization's security policy requires that a particular CipherSpec be used, then you must obtain suitable digital certificates.

For more information on the relationship between CipherSpecs and digital certificates, refer to "Digital certificates and CipherSpec compatibility in IBM MQ" on page 419

Certificate validation policies

The IETF RFC 5280 standard specifies a series of certificate validation rules which compliant application software must implement in order to prevent impersonation attacks. A set of certificate validation rules is known as a certificate validation policy. For more information about certificate validation policies in IBM MQ, see "Certificate validation policies in IBM MQ" on page 418.

Planning for certificate revocation checking

Allowing multiple certificates from different certificate authorities potentially causes unnecessary additional certificate revocation checking.

In particular, if you have explicitly configured the use of a revocation server from a particular CA, for example by using an AUTHINFO object or Authentication information record (MQAIR) structure, a revocation check fails when presented with a certificate from a different CA.

You should avoid explicit certificate revocation server configuration. Instead, you should enable implicit checking where each certificate contains its own revocation server location in a certificate extension, for example, CRL Distribution Point, or OCSP AuthorityInfoAccess.

For more information, see OCSPCheckExtensions and CDPCheckExtensions.

Commands and attributes for SSL and TLS support

The Secure Sockets Layer (SSL) and Transport Layer Security (TLS) protocols provide channel security, with protection against eavesdropping, tampering, and impersonation. IBM MQ support for SSL and TLS enables you to specify, on the channel definition, that a particular channel uses SSL or TLS security. You can also specify details of the type of security you want, such as the encryption algorithm you want to use.

- The following MQSC commands support SSL and TLS:

  ALTER AUTHINFO
  Modifies the attributes of an authentication information object.

  DEFINE AUTHINFO
  Creates an authentication information object.

  DELETE AUTHINFO
  Deletes an authentication information object.

  DISPLAY AUTHINFO
  Displays the attributes for a specific authentication information object.

- The following queue manager parameters support SSL and TLS:

  CERTLABL
  Defines a personal certificate label to use.

  SSLCRLNL
  The SSLCRLNL attribute specifies a namelist of authentication information objects which are used to provide certificate revocation locations to allow enhanced TLS/SSL certificate checking.

  SSLCRYP
  On Windows , UNIX and Linux systems, sets the **SSLCryptoHardware** queue manager attribute. This attribute is the name of the parameter string that you can use to configure the cryptographic hardware you have on your system.

SSLEV
: Determines whether an SSL/TLS event message is reported if a channel using SSL/TLS fails to establish an SSL/TLS connection.

SSLFIPS
: Specifies whether only FIPS-certified algorithms are to be used if cryptography is carried out in IBM MQ , rather than in cryptographic hardware. If cryptographic hardware is configured, the cryptographic modules provided by the hardware product are used, and these might be FIPS-certified to a particular level. This depends on the hardware product in use.

SSLKEYR
: On Windows, UNIX and Linux systems, associates a key repository with a queue manager. The key database is held in a *GSKit* key database. The IBM Global Security Kit (GSKit) enables you to use SSL security on Windows , UNIX and Linux systems.

SSLRKEYC
: The number of bytes to be sent and received within an SSL/TLS conversation before the secret key is renegotiated. The number of bytes includes control information sent by the MCA.

- The following channel parameters support SSL and TLS:

CERTLABL
: Defines a personal certificate label to use.

SSLCAUTH
: Defines whether IBM MQ requires and validates a certificate from the SSL/TLS client.

SSLCIPH
: Specifies the encryption strength and function (CipherSpec), for example TLS_RSA_WITH_AES_128_CBC_SHA. The CipherSpec must match at both ends of channel.

SSLPEER
: Specifies the distinguished name (unique identifier) of allowed partners.

This section describes the **setmqaut** , **dspmqaut** , **dmpmqaut** , **rcrmqobj** , **rcdmqimg** , and **dspmqfls** commands to support the authentication information object. It also describes the iKeycmd command for managing certificates on UNIX and Linux systems, and the runmqakm tool for managing certificates on UNIX, Linux and Windows systems. See the following sections:

- setmqaut
- dspmqaut
- dmpmqaut
- rcrmqobj
- rcdmqimg
- dspmqfls
- Managing keys and certificates

IBM MQ for z/OS server connection channel

The IBM MQ for z/OS SVRCONN channel is not secure without implementing channel authentication, or adding a security exit using SSL or TLS. SVRCONN channels do not have a security exit defined by default.

Security concerns

SVRCONN channels are not secure as initially defined, SYSTEM.DEF.SVRCONN for example. To secure a SVRCONN channel you must set up channel authentication using the SET CHLAUTH command, or install a security exit and implement SSL, or TLS.

You must use a publicly available sample security exit, write a security exit yourself, or purchase a security exit.

There are several samples available that you can use as a good starting point for writing your own SVRCONN channel security exit.

In IBM MQ for z/OS, the member CSQ4BCX3 in your hlq.SCSQC37S library is a security exit sample written in the C language. Sample CSQ4BCX3 is also shipped pre-compiled in your hlq.SCSQAUTH library.

You can implement the CSQ4BCX3 sample exit by copying the compiled member hlq.SCSQAUTH(CSQ4BCX3) into a load library that is allocated to the CSQXLIB DD in your CHIN Proc. Note that the CHIN requires the load library to be set as "Program Controlled".

Alter your SVRCONN channel to set CSQ4BCX3 as the security exit.

When a client connects using that SVRCONN channel, CSQ4BCX3 will authenticate using the RemoteUserIdentifier and RemotePassword pair from MQCD. If authentication is successful it will copy RemoteUserIdentifier into MCAUserIdentifier, changing the identity context of the thread.

If you are writing an MQ Java client you can use pop-ups to query the user and set MQEnvironment.userID and MQEnvironment.password. These values will be passed when the connection is made.

Now that you have a functional security exit, there is the additional concern that the userid and password are being transmitted in plain text across the network when the connection is made, as are the contents of any subsequent MQ messages. You can use SSL to encrypt this initial connection information as well as the contents of any MQ messages.

Example

To secure the MQ Explorer SVRCONN channel SYSTEM.ADMIN.SVRCONN complete the following steps:

1. Copy hlq.SCSQAUTH(CSQ4BCX3) into a load library that is allocated to the CSQXLIB DD in the CHINIT Proc.
2. Verify that load library is Program Controlled.
3. Alter the SYSTEM ADMIN.SVRCONN to use security exit CSQ4BCX3.
4. In MQ Explorer, right-click the z/OS Queue Manager name, select **Connection Details** > **Properties** > **Userid** and enter your z/OS user ID.
5. Connect to the z/OS Queue Manager by entering a password.

Additional information

For exit CSQ4BCX3 to run in a Program Controlled environment, everything loaded into the CHIN address space must be loaded from a Program Controlled library, for example, all libraries in STEPLIB and any libraries named on CSQXLIB DD. To set a load library as Program Controlled issue RACF commands. In the following example the load library name is MY.TEST.LOADLIB.

```
RALTER PROGRAM * ADDMEM('MY.TEST.LOADLIB'//NOPADCHK)
SETROPTS WHEN(PROGRAM)REFRESH
```

To alter the SVRCONN channel to implement CSQ4BCX3, issue the following MQ command:

```
ALTER CHANNEL( SYSTEM ADMIN.SVRCONN) CHLTYPE(SVRCONN) SECYEXIT(CSQ4BCX3)
```

In the example above, the SVRCONN channel name being used is SYSTEM ADMIN.SVRCONN.

See "Channel exit programs" on page 476 for more information about channel exits.

Writing channel exit programs on z/OS

SNA LU 6.2 security services

SNA LU 6.2 offers session level cryptography, session level authentication, and conversation level authentication.

Note: This collection of topics assumes that you have a basic understanding of Systems Network Architecture (SNA). The other documentation referred to in this section contains a brief introduction to the relevant concepts and terminology. If you require a more comprehensive technical introduction to SNA, see *Systems Network Architecture Technical Overview*, GC30-3073.

SNA LU 6.2 provides three security services:

- Session level cryptography
- Session level authentication
- Conversation level authentication

For session level cryptography and session level authentication, SNA uses the *Data Encryption Standard (DES)* algorithm. The DES algorithm is a block cipher algorithm, which uses a symmetric key for encrypting and decrypting data. Both the block and the key are 8 bytes in length.

Session level cryptography

Session level cryptography encrypts and decrypts session data using the DES algorithm. It can therefore be used to provide a link level confidentiality service on SNA LU 6.2 channels.

Logical units (LUs) can provide mandatory (or required) data cryptography, selective data cryptography, or no data cryptography.

On a *mandatory cryptographic session*, an LU encrypts all outbound data request units and decrypts all inbound data request units.

On a *selective cryptographic session*, an LU encrypts only the data request units specified by the sending transaction program (TP). The sending LU signals that the data is encrypted by setting an indicator in the request header. By checking this indicator, the receiving LU can tell which request units to decrypt before passing them on to the receiving TP.

In an SNA network, IBM MQ MCAs are transaction programs. MCAs do not request encryption for any data that they send. Selective data cryptography is not an option therefore; only mandatory data cryptography or no data cryptography is possible on a session.

For information about how to implement mandatory data cryptography, see the documentation for your SNA subsystem. Refer to the same documentation for information about stronger forms of encryption that might be available for use on your platform, such as Triple DES 24-byte encryption on z/OS.

For more general information about session level cryptography, see *Systems Network Architecture LU 6.2 Reference: Peer Protocols*, SC31-6808.

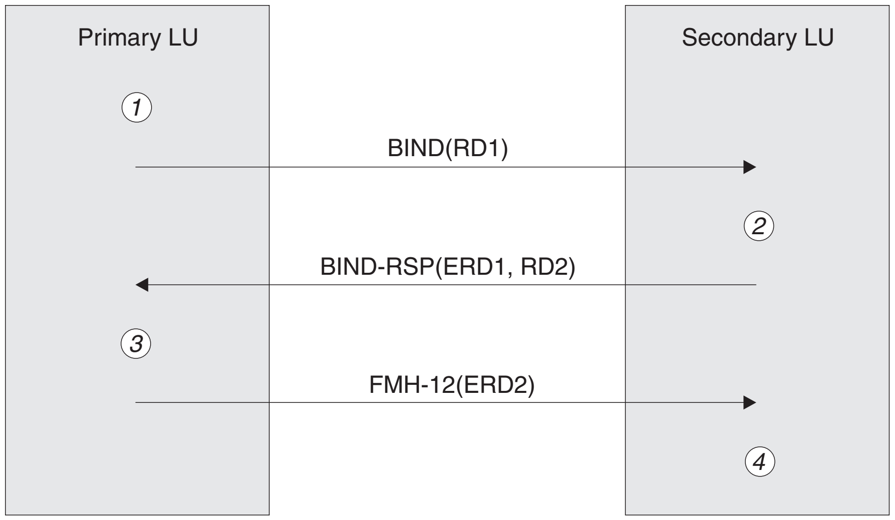
Session level authentication

Session level authentication is a session level security protocol that enables two LUs to authenticate each other while they are activating a session. It is also known as *LU-LU verification*.

Because an LU is effectively the "gateway" into a system from the network, you might consider this level of authentication to be sufficient in certain circumstances. For example, if your queue manager needs to exchange messages with a remote queue manager that is running in a controlled and trusted environment, you might be prepared to trust the identities of the remaining components of the remote system after the LU has been authenticated.

Session level authentication is achieved by each LU verifying its partner's password. The password is called an *LU-LU password* because one password is established between each pair of LUs. The way that an LU-LU password is established is implementation dependent and outside the scope of SNA.

Figure 65 illustrates the flows for session level authentication.



Legend:

BIND	=	BIND request unit
BIND-RSP	=	BIND response unit
ERD	=	Encrypted random data
FMH-12	=	Function Management Header 12
RD	=	Random data

Figure 65. Flows for session level authentication

The protocol for session level authentication is as follows. The numbers in the procedure correspond to the numbers in Figure 65.

1. The primary LU generates a random data value (RD1) and sends it to the secondary LU in the BIND request.

2. When the secondary LU receives the BIND request with the random data, it encrypts the data using the DES algorithm with its copy of the LU-LU password as the key. The secondary LU then generates a second random data value (RD2) and sends it, with the encrypted data (ERD1), to the primary LU in the BIND response.
3. When the primary LU receives the BIND response, it computes its own version of the encrypted data from the random data it generated originally. It does this by using the DES algorithm with its copy of the LU-LU password as the key. It then compares its version with the encrypted data that it received in the BIND response. If the two values are the same, the primary LU knows that the secondary LU has the same password as it does and the secondary LU is authenticated. If the two values do not match, the primary LU terminates the session.

   The primary LU then encrypts the random data that it received in the BIND response and sends the encrypted data (ERD2) to the secondary LU in a Function Management Header 12 (FMH-12).
4. When the secondary LU receives the FMH-12, it computes its own version of the encrypted data from the random data it generated. It then compares its version with the encrypted data that it received in the FMH-12. If the two values are the same, the primary LU is authenticated. If the two values do not match, the secondary LU terminates the session.

In an enhanced version of the protocol, which provides better protection against man in the middle attacks, the secondary LU computes a DES Message Authentication Code (MAC) from RD1, RD2, and the fully qualified name of the secondary LU, using its copy of the LU-LU password as the key. The secondary LU sends the MAC to the primary LU in the BIND response instead of ERD1.

The primary LU authenticates the secondary LU by computing its own version of the MAC, which it compares with the MAC received in the BIND response. The primary LU then computes a second MAC from RD1 and RD2, and sends the MAC to the secondary LU in the FMH-12 instead of ERD2.

The secondary LU authenticates the primary LU by computing its own version of the second MAC, which it compares with the MAC received in the FMH-12.

For information about how to configure session level authentication, see the documentation for your SNA subsystem. For more general information about session level authentication, see *Systems Network Architecture LU 6.2 Reference: Peer Protocols*, SC31-6808.

Conversation level authentication

When a local TP attempts to allocate a conversation with a partner TP, the local LU sends an attach request to the partner LU, asking it to attach the partner TP. Under certain circumstances, the attach request can contain security information, which the partner LU can use to authenticate the local TP. This is known as *conversation level authentication*, or *end user verification*.

The following topics describe how IBM MQ provides support for conversation level authentication.

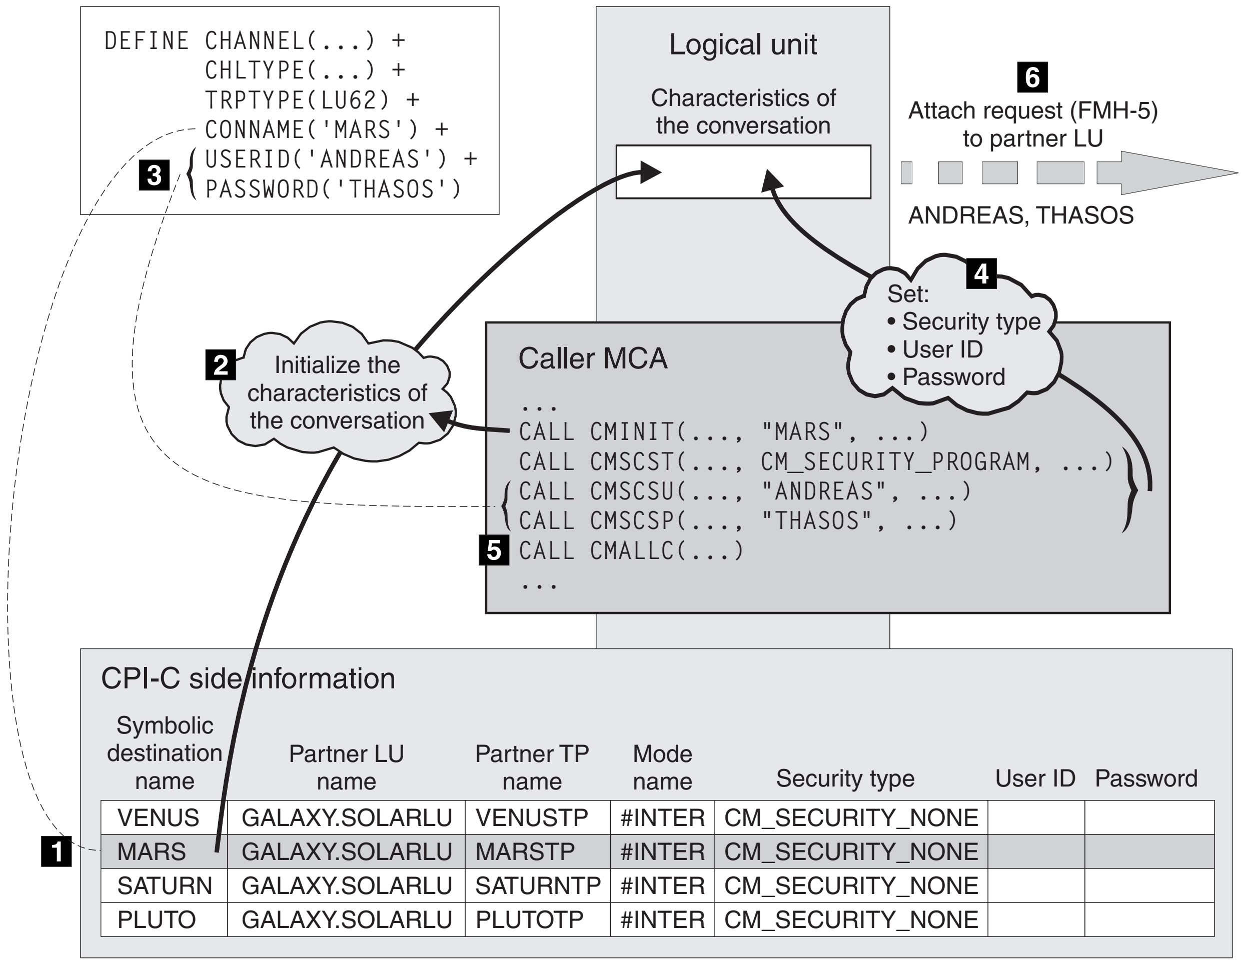
For more information about conversation level authentication, see *Systems Network Architecture LU 6.2 Reference: Peer Protocols*, SC31-6808. For information specific to z/OS, see *z/OS MVS Planning: APPC/MVS Management*, SA22-7599.

For more information about CPI-C, see *Common Programming Interface Communications CPI-C Specification*, SC31-6180. For more information about APPC/MVS TP Conversation Callable Services, see *z/OS MVS Programming: Writing Transaction Programs for APPC/MVS*, SA22-7621.

Support for conversation level authentication in IBM MQ on : IBM i,UNIX systemsWindows

Use this topic to gain an overview of how conversation level authentication works, on platforms other than z/OS.

The support for conversation level authentication in IBM MQ for IBM i, IBM MQ on UNIX systems, and IBM MQ for Windows is illustrated in Figure 66. The numbers in the diagram correspond to the numbers in the description that follows.



```
DEFINE CHANNEL(...) +
       CHLTYPE(...) +
       TRPTYPE(LU62) +
       CONNAME('MARS') +
     3 USERID('ANDREAS') +
       PASSWORD('THASOS')
```

```
Caller MCA
...
CALL CMINIT(..., "MARS", ...)
CALL CMSCST(..., CM_SECURITY_PROGRAM, ...)
CALL CMSCSU(..., "ANDREAS", ...)
CALL CMSCSP(..., "THASOS", ...)
5 CALL CMALLC(...)
...
```

CPI-C side information

	Symbolic destination name	Partner LU name	Partner TP name	Mode name	Security type	User ID	Password
	VENUS	GALAXY.SOLARLU	VENUSTP	#INTER	CM_SECURITY_NONE		
1	MARS	GALAXY.SOLARLU	MARSTP	#INTER	CM_SECURITY_NONE		
	SATURN	GALAXY.SOLARLU	SATURNTP	#INTER	CM_SECURITY_NONE		
	PLUTO	GALAXY.SOLARLU	PLUTOTP	#INTER	CM_SECURITY_NONE

Initialize the characteristics of the conversation

Figure 66. IBM MQ support for conversation level authentication

On IBM i, UNIX systems, and Windows systems, an MCA uses Common Programming Interface Communications (CPI-C) calls to communicate with a partner MCA across an SNA network. In the channel definition at the caller end of a channel, the value of the CONNAME parameter is a symbolic destination name, which identifies a CPI-C side information entry (1). This entry specifies:

- The name of the partner LU
- The name of the partner TP, which is a responder MCA
- The name of the mode to be used for the conversation

A side information entry can also specify the following security information:

- A security type.

The commonly implemented security types are CM_SECURITY_NONE, CM_SECURITY_PROGRAM, and CM_SECURITY_SAME, but others are defined in the CPI-C specification.
- A user ID.
- A password.

A caller MCA prepares to allocate a conversation with a responder MCA by issuing the CPI-C call CMINIT, using the value of CONNAME as one of the parameters on the call. The CMINIT call identifies, for the benefit of the local LU, the side information entry that the MCA intends to use for the conversation. The local LU uses the values in this entry to initialize the characteristics of the conversation (2).

The caller MCA then checks the values of the USERID and PASSWORD parameters in the channel definition (3). If USERID is set, the caller MCA issues the following CPI-C calls (4):
- CMSCST, to set the security type for the conversation to CM_SECURITY_PROGRAM.
- CMSCSU, to set the user ID for the conversation to the value of USERID.
- CMSCSP, to set the password for the conversation to the value of PASSWORD. CMSCSP is not called unless PASSWORD is set.

The security type, user ID, and password set by these calls override any values acquired previously from the side information entry.

The caller MCA then issues the CPI-C call CMALLC to allocate the conversation (5). In response to this call, the local LU sends an attach request (Function Management Header 5, or FMH-5) to the partner LU (6).

If the partner LU will accept a user ID and a password, the values of USERID and PASSWORD are included in the attach request. If the partner LU will not accept a user ID and a password, the values are not included in the attach request. The local LU discovers whether the partner LU will accept a user ID and a password as part of an exchange of information when the LUs bind to form a session.

In a later version of the attach request, a password substitute can flow between the LUs instead of a clear password. A password substitute is a DES Message Authentication Code (MAC), or an SHA-1 message digest, formed from the password. Password substitutes can be used only if both LUs support them.

When the partner LU receives an incoming attach request containing a user ID and a password, it might use the user ID and password for the purposes of identification and authentication. By referring to access control lists, the partner LU might also determine whether the user ID has the authority to allocate a conversation and attach the responder MCA.

In addition, the responder MCA might run under the user ID included in the attach request. In this case, the user ID becomes the default user ID for the responder MCA and is used for authority checks when the MCA attempts to connect to the queue manager. It might also be used for authority checks subsequently when the MCA attempts to access the queue manager's resources.

The way in which a user ID and a password in an attach request can be used for identification, authentication, and access control is implementation dependent. For information specific to your SNA subsystem, refer to the appropriate documentation.

If USERID is not set, the caller MCA does not call CMSCST, CMSCSU, and CMSCSP. In this case, the security information that flows in an attach request is determined solely by what is specified in the side information entry and what the partner LU will accept.

Conversation level authentication and IBM MQ for z/OS

Use this topic to gain an overview of how conversation level authentication works, on z/OS.

On IBM MQ for z/OS, MCAs do not use CPI-C. Instead, they use APPC/MVS TP Conversation Callable Services, an implementation of Advanced Program-to-Program Communication (APPC), which has some CPI-C features. When a caller MCA allocates a conversation, a security type of SAME is specified on the call. Therefore, because an APPC/MVS LU supports persistent verification only for inbound conversations, not for outbound conversations, there are two possibilities:

- If the partner LU trusts the APPC/MVS LU and will accept an already verified user ID, the APPC/MVS LU sends an attach request containing:
  - The channel initiator address space user ID
  - A security profile name, which, if RACF is used, is the name of the current connect group of the channel initiator address space user ID
  - An already verified indicator
- If the partner LU does not trust the APPC/MVS LU and will not accept an already verified user ID, the APPC/MVS LU sends an attach request containing no security information.

On IBM MQ for z/OS, the USERID and PASSWORD parameters on the DEFINE CHANNEL command cannot be used for a message channel and are valid only at the client connection end of an MQI channel. Therefore, an attach request from an APPC/MVS LU never contains values specified by these parameters.

Security for queue manager clusters

Though queue manager clusters can be convenient to use, you must pay special attention to their security.

A *queue manager cluster* is a network of queue managers that are logically associated in some way. A queue manager that is a member of a cluster is called a *cluster queue manager*.

A queue that belongs to a cluster queue manager can be made known to other queue managers in the cluster. Such a queue is called a *cluster queue*. Any queue manager in a cluster can send messages to cluster queues without needing any of the following:

- An explicit remote queue definition for each cluster queue
- Explicitly defined channels to and from each remote queue manager
- A separate transmission queue for each outbound channel

You can create a cluster in which two or more queue managers are clones. This means that they have instances of the same local queues, including any local queues declared as cluster queues, and can support instances of the same server applications.

When an application connected to a cluster queue manager sends a message to a cluster queue that has an instance on each of the cloned queue managers, IBM MQ decides which queue manager to send it to. When many applications send messages to the cluster queue, IBM MQ balances the workload across each of the queue managers that have an instance of the queue. If one of the systems hosting a cloned queue manager fails, IBM MQ continues to balance the workload across the remaining queue managers until the system that failed is restarted.

If you are using queue manager clusters, you need to consider the following security issues:

- Allowing only selected queue managers to send messages to your queue manager
- Allowing only selected users of a remote queue manager to send messages to a queue on your queue manager
- Allowing applications connected to your queue manager to send messages only to selected remote queues

These considerations are relevant even if you are not using clusters, but they become more important if you are using clusters.

If an application can send messages to one cluster queue, it can send messages to any other cluster queue without needing additional remote queue definitions, transmission queues, or channels. It therefore becomes more important to consider whether you need to restrict access to the cluster queues on your queue manager, and to restrict the cluster queues to which your applications can send messages.

There are some additional security considerations, which are relevant only if you are using queue manager clusters:

- Allowing only selected queue managers to join a cluster
- Forcing unwanted queue managers to leave a cluster

For more information about all these considerations, see Keeping clusters secure. z/OS For considerations specific to IBM MQ for z/OS, see "Security in queue manager clusters on z/OS" on page 643.

Related tasks:
"Preventing queue managers receiving messages" on page 817
You can prevent a cluster queue manager from receiving messages it is unauthorized to receive by using exit programs.

Security for IBM MQ Publish/Subscribe

There are additional security considerations if you are using IBM MQ Publish/Subscribe.

In a publish/subscribe system, there are two types of application: publisher and subscriber. *Publishers* supply information in the form of IBM MQ messages. When a publisher publishes a message, it specifies a *topic*, which identifies the subject of the information inside the message.

Subscribers are the consumers of the information that is published. A subscriber specifies the topics it is interested in by subscribing to them.

The *queue manager* is an application supplied with IBM MQ Publish/Subscribe. It receives published messages from publishers and subscription requests from subscribers, and routes the published messages to the subscribers. A subscriber is sent messages only on those topics to which it has subscribed.

For more information, see Publish/subscribe security.

Multicast security

Use this information to understand why security processes might be needed with IBM MQ Multicast.

IBM MQ Multicast does not have in-built security. Security checks are handled in the queue manager at MQOPEN time and the MQMD field setting is handled by the client. Some applications in the network might not be IBM MQ applications (For example, LLM applications, see Multicast interoperability with IBM MQ Low Latency Messaging for more information), therefore you might need to implement your own security procedures because receiving applications cannot be certain of the validity of context fields.

There are three security processes to consider:

Access control

Access control in IBM MQ is based on user IDs. For more information on this subject, see "Access control for clients" on page 467.

Network security

An isolated network might be a viable security option to prevent fake messages. It is possible for an application on the multicast group address to publish malicious messages using native communication functions, which are indistinguishable from MQ messages because they come from an application on the same multicast group address.

It is also possible for a client on the multicast group address to receive messages that were intended for other clients on the same multicast group address.

Isolating the multicast network ensures that only valid clients and applications have access. This security precaution can prevent malicious messages from coming in, and confidential information from going out.

For information about multicast group network addresses, see: Setting the appropriate network for multicast traffic

Digital signatures

A digital signature is formed by encrypting a representation of a message. The encryption uses the private key of the signatory and, for efficiency, usually operates on a message digest rather than the message itself. Digitally signing a message before an MQPUT is a good security precaution, but this process might have a detrimental effect on performance if there is a large volume of messages.

Digital signatures vary with the data being signed. If two different messages are signed digitally by the same entity, the two signatures differ, but both signatures can be verified with the same public key, that is, the public key of the entity that signed the messages.

As mentioned previously in this section, it might be possible for an application on the multicast group address to publish malicious messages using native communication functions, which are indistinguishable from MQ messages. Digital signatures provide proof of origin, and only the sender knows the private key, which provides strong evidence that the sender is the originator of the message.

For more information on this subject, see "Cryptographic concepts" on page 380.

Firewalls and Internet pass-thru

You would normally use a firewall to prevent access from hostile IP addresses, for example in a Denial of Service attack. However, you might need to temporarily block IP addresses within IBM MQ, perhaps while you wait for a security administrator to update the firewall rules.

To block one or more IP addresses, create a channel authentication record of type BLOCKADDR or ADDRESSMAP. For more information, see “Blocking specific IP addresses” on page 762.

Security for IBM MQ internet pass-thru

Internet pass-thru can simplify communication through a firewall, but this has security implications.

IBM MQ internet pass-thru is an IBM MQ base product extension that is supplied in SupportPac MS81.

IBM MQ internet pass-thru enables two queue managers to exchange messages, or an IBM MQ client application to connect to a queue manager, over the Internet without requiring a direct TCP/IP connection. This is useful if a firewall prohibits a direct TCP/IP connection between two systems. It makes the passage of IBM MQ channel protocol flows into and out of a firewall simpler and more manageable by tunnelling the flows inside HTTP or by acting as a proxy. Using the Secure Sockets Layer (SSL), it can also be used to encrypt and decrypt messages that are sent over the Internet.

When your IBM MQ system communicates with IPT, unless you are using SSLProxyMode in IPT, ensure that the CipherSpec used by IBM MQ matches the CipherSuite used by IPT:

- When IPT is acting as the SSL or TLS server and IBM MQ is connecting as the SSL or TLS client, the CipherSpec used by IBM MQ must correspond to a CipherSuite that is enabled in the relevant IPT key ring.
- When IPT is acting as the SSL or TLS client and is connecting to an IBM MQ SSL or TLS server, the IPT CipherSuite must match the CipherSpec defined on the receiving IBM MQ channel.

If you migrate from IPT to the integrated IBM MQ SSL and TLS support, transfer the digital certificates from IPT Using iKeyman.

For more information about IBM MQ internet pass-thru, see *MS81: IBM MQ internet pass-thru*, available from the following address: http://www.ibm.com/software/integration/support/supportpacs/

IBM MQ for z/OS security implementation checklist

This topic gives a step-by-step procedure you can use to work out and define the security implementation for each of your IBM MQ queue managers.

RACF provides definitions for the IBM MQ security classes in its supplied static Class Descriptor Table (CDT). As you work through the checklist, you can determine which of these classes your setup requires. You must ensure that they are activated as described in "RACF security classes" on page 567.

Refer to other sections for details, in particular "Profiles used to control access to IBM MQ resources" on page 577.

If you require security checking, follow this checklist to implement it:

1. Activate the RACF MQADMIN (uppercase profiles) or MXADMIN (mixed case profiles) class.
   - Do you want security at queue-sharing group level, queue-manager level, or a combination of both?

     See, "Profiles to control queue-sharing group or queue manager level security" on page 572.
2. Do you need connection security?
   - **Yes**: Activate the MQCONN class. Define appropriate connection profiles at either queue manager level or queue-sharing group level in the MQCONN class. Then permit the appropriate users or groups access to these profiles.

     Note: Only users of the **MQCONN** API request or CICS or IMS address space user IDs need to have access to the corresponding connection profile.
   - **No**: Define an hlq.NO.CONNECT.CHECKS profile at either queue manager level or queue-sharing group level in the MQADMIN or MXADMIN class.
3. Do you need security checking on commands?
   - **Yes**: Activate the MQCMDS class. Define appropriate command profiles at either queue manager level or queue-sharing group level in the MQCMDS class. Then permit the appropriate users or groups access to these profiles.

     If you are using a queue-sharing group, you might need to include the user IDs used by the queue manager itself and the channel initiator. See "Setting up IBM MQ for z/OS resource security" on page 634.
   - **No**: Define an hlq.NO.CMD.CHECKS profile for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
4. Do you need security on the resources used in commands?
   - **Yes**: Ensure the MQADMIN or MXADMIN class is active. Define appropriate profiles for protecting resources on commands at either queue manager level or queue-sharing group level in the MQADMIN or MXADMIN class. Then permit the appropriate users or groups access to these profiles. Set the CMDUSER parameter in CSQ6SYSP to the default user ID to be used for command security checks.

     If you are using a queue-sharing group, you might need to include the user IDs used by the queue manager itself and the channel initiator. See "Setting up IBM MQ for z/OS resource security" on page 634.
   - **No**: Define an hlq.NO.CMD.RESC.CHECKS profile for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
5. Do you need queue security?

- **Yes**: Activate the MQQUEUE or MXQUEUE class. Define appropriate queue profiles for the required queue manager or queue-sharing group in the MQQUEUE or MXQUEUEclass. Then permit the appropriate users or groups access to these profiles.
- **No**: Define an hlq.NO.QUEUE.CHECKS profile for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.

6. Do you need process security?
   - **Yes**: Activate the MQPROC or MXPROC class. Define appropriate process profiles at either queue manager or queue-sharing group level and permit the appropriate users or groups access to these profiles.
   - **No**: Define an hlq.NO.PROCESS.CHECKS profile for the appropriate queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
7. Do you need namelist security?
   - **Yes**: Activate the MQNLIST or MXNLISTclass. Define appropriate namelist profiles at either queue manager level or queue-sharing group level in the MQNLIST or MXNLIST class. Then permit the appropriate users or groups access to these profiles.
   - **No**: Define an hlq.NO.NLIST.CHECKS profile for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
8. Do you need topic security?
   - **Yes**: Activate the MXTOPIC class. Define appropriate topic profiles at either queue manager level or queue-sharing group level in the MXTOPIC class. Then permit the appropriate users or groups access to these profiles.
   - **No**: Define an hlq.NO.TOPIC.CHECKS profile for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
9. Do any users need to protect the use of the **MQOPEN** or **MQPUT1** options relating to the use of context?
   - **Yes**: Ensure the MQADMIN or MXADMIN class is active. Define hlq.CONTEXT.queuename profiles at the queue, queue manager, or queue-sharing group level in the MQADMIN or MXADMIN class. Then permit the appropriate users or groups access to these profiles.
   - **No**: Define an hlq.NO.CONTEXT.CHECKS profile for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
10. Do you need to protect the use of alternative user IDs?
    - **Yes**: Ensure the MQADMIN or MXADMIN class is active. Define the appropriate hlq.ALTERNATE.USER. *alternateuserid* profiles for the required queue manager or queue-sharing group and permit the required users or groups access to these profiles.
    - **No**: Define the profile hlq.NO.ALTERNATE.USER.CHECKS for the required queue manager or queue-sharing group in the MQADMIN or MXADMIN class.
11. Do you need to tailor which user IDs are to be used for resource security checks through RESLEVEL?
    - **Yes**: Ensure the MQADMIN or MXADMIN class is active. Define an hlq.RESLEVEL profile at either queue manager level or queue-sharing group level in the MQADMIN or MXADMIN class. Then permit the required users or groups access to the profile.
    - **No**: Ensure that no generic profiles exist in the MQADMIN or MXADMIN class that can apply to hlq.RESLEVEL. Define an hlq.RESLEVEL profile for the required queue manager or queue-sharing group and ensure that no users or groups have access to it.
12. Do you need to 'timeout' unused user IDs from IBM MQ ?
    - **Yes**: Determine what timeout values you would like to use and issue the MQSC ALTER SECURITY command to change the TIMEOUT and INTERVAL parameters.
    - **No**: Issue the MQSC ALTER SECURITY command to set the INTERVAL value to zero.

Note: Update the CSQINP1 initialization input data set used by your subsystem so that the MQSC ALTER SECURITY command is issued automatically when the queue manager is started.

13. Do you use distributed queuing?
    - **Yes**: Use channel authentication records. For more information, see "Channel authentication records" on page 424.
    - You can also determine the appropriate MCAUSER attribute value for each channel, or provide suitable channel security exits.
14. Do you want to use the Secure Sockets Layer (SSL)?
    - **Yes**: To specify that any user presenting an SSL/TLS personal certificate containing a specified DN is to use a specific MCAUSER, set a channel authentication record of type SSLPEERMAP. You can specify a single distinguished name or a pattern including wildcards.
    - Plan your SSL infrastructure. Install the System SSL feature of z/OS. In RACF, set up your certificate name filters (CNFs), if you are using them, and your digital certificates. Set up your SSL key ring. Ensure that the SSLKEYR queue manager attribute is nonblank and points to your SSL key ring. Also ensure that the value of SSLTASKS is at least 2.
    - **No**: Ensure that SSLKEYR is blank, and SSLTASKS is zero.

    For further details about SSL, see "SSL and TLS security protocols in IBM MQ" on page 397.
15. Do you use clients?
    - **Yes**: Use channel authentication records.
    - You can also determine the appropriate MCAUSER attribute value for each server-connection channel, or provide suitable channel security exits if required.
16. Check your switch settings.

    IBM MQ issues messages when the queue manager is started that display your security settings. Use these messages to determine whether your switches are set correctly.
17. Do you send passwords from client applications?
    - **Yes**: Ensure that the z/OS feature is installed and Integrated Cryptographic Service Facility (ICSF) is started for the best protection.
    - **No**: You can ignore the error message reporting that ICSF has not started.

    For further information about ICSF see "Using the Integrated Cryptographic Service Facility (ICSF)" on page 643

Setting up security

This collection of topics contains information specific to different operating systems, and to the use of clients.

Setting up security on Windows, UNIX and Linux systems

Security considerations specific to Windows, UNIX and Linux systems.

IBM MQ queue managers transfer information that is potentially valuable, so you need to use an authority system to ensure that unauthorized users cannot access your queue managers. Consider the following types of security controls:

Who can administer IBM MQ
: You can define the set of users who can issue commands to administer IBM MQ.

Who can use IBM MQ objects
: You can define which users (usually applications) can use MQI calls and PCF commands to do the following:
- Who can connect to a queue manager.
- Who can access objects (queues, process definitions, namelists, channels, client connection channels, listeners, services, and authentication information objects), and what type of access they have to those objects.
- Who can access IBM MQ messages.
- Who can access the context information associated with a message.

Channel security
: You need to ensure that channels used to send messages to remote systems can access the required resources.

You can use standard operating facilities to grant access to program libraries, MQI link libraries, and commands. However, the directory containing queues and other queue manager data is private to IBM MQ; do not use standard operating system commands to grant or revoke authorizations to MQI resources.

Connecting to IBM MQ using Terminal Services

The **`Create global objects`** user right can cause problems if you are using Terminal Services.

If you are connecting to a Windows system by using Terminal Services and you have problems creating or starting a queue manager, this might be because of the user right, **`Create global objects`**, in recent versions of Windows.

The **`Create global objects`** user right limits the users authorized to create objects in the global namespace. In order for an application to create a global object, it must either be running in the global namespace, or the user under which the application is running must have the **`Create global objects`** user right applied to it.

Administrators have the **`Create global objects`** user right applied by default, so an administrator can create and start queue managers when connected by using Terminal Services without altering the user rights.

If the various methods of administering IBM MQ do no work when you use terminal services, try setting the **`Create global objects`** user right:

1. Open the Administrative Tools panel:

   Windows Server 2008 and Windows Server 2012
   : Access this panel using **Control Panel** > **System and Maintenance** > **Administrative Tools**.

   Windows 7 and Windows 8.1
   : Access this panel using **Administrative Tools** > **Computer Management**
2. Double-click **Local Security Policy**.
3. Expand **Local Policies** .
4. Click **User Rights Assignment** .
5. Add the new user or group to the `Create global objects` policy.

Creating and managing groups on Windows

These instructions lead you through the process of administering groups on a workstation or member server machine.

For domain controllers, users and groups are administered through Active Directory. For more details on using Active Directory refer to the appropriate operating system instructions.

Any changes you make to a principal's group membership are not recognized until the queue manager is restarted, or you issue the MQSC command REFRESH SECURITY (or the PCF equivalent).

Use the Computer Management panel to work with user and groups. Any changes made to the current logged on user might not be effective until the user logs in again.

Windows Server 2008 and Windows Server 2012
: Access this panel using **Control Panel** > **System and Maintenance** > **Administrative Tools** > **Computer Management**.

Windows 7 and Windows 8.1
: Access this panel using **Administrative Tools** > **Computer Management**

Creating a group on Windows

Create a group by using the control panel.

Procedure

1. Open the control panel
2. Double-click **Administrative Tools**. The Administrative Tools panel opens.
3. Double-click **Computer Management**. The Computer Management panel opens.
4. Expand **Local Users and Groups**.
5. Right-click **Groups**, and select **New Group...**. The New Group panel is displayed.
6. Type an appropriate name in the Group name field, then click **Create**.
7. Click **Close**.

Adding a user to a group on Windows

Add a user to a group by using the control panel.

Procedure

1. Open the control panel
2. Double-click **Administrative Tools**. The Administrative Tools panel opens.
3. Double-click **Computer Management**. The Computer Management panel opens.
4. From the Computer Management panel, expand **Local Users and Groups**.
5. Select **Users**
6. Double-click the user that you want to add to a group. The user properties panel is displayed.
7. Select the **Member Of** tab.
8. Select the group that you want to add the user to. If the group you want is not visible:
   a. Click **Add...**. The Select Groups panel is displayed.
   b. Click **Locations...**. The Locations panel is displayed.
   c. Select the location of the group you want to add the user to from the list and click **OK**.
   d. Type the group name in the field provided.

      Alternatively, click **Advanced...** and then **Find Now** to list the groups available in the currently selected location. From here, select the group you want to add the user to and click **OK**.
   e. Click **OK**. The user properties panel is displayed, showing the group you added.
   f. Select the group.
9. Click **OK**. The Computer Management panel is displayed.

Displaying who is in a group on Windows

Display the members of a group by using the control panel.

Procedure

1. Open the control panel
2. Double-click **Administrative Tools**. The Administrative Tools panel opens.
3. Double-click **Computer Management**. The Computer Management panel opens.
4. From the Computer Management panel, expand **Local Users and Groups**.
5. Select **Groups**.
6. Double-click a group. The group properties panel is displayed. The group properties panel is displayed.

Results

The group members are displayed.

Removing a user from a group on Windows

Remove a user from a group by using the control panel.

Procedure

1. Open the control panel
2. Double-click **Administrative Tools**. The Administrative Tools panel opens.
3. Double-click **Computer Management**. The Computer Management panel opens.
4. From the Computer Management panel, expand **Local Users and Groups**.
5. Select **Users**.
6. Double-click the user that you want to add to a group. The user properties panel is displayed.
7. Select the **Member Of** tab.
8. Select the group that you want to remove the user from, then click **Remove**.
9. Click **OK**. The Computer Management panel is displayed.

Results

You have now removed the user from the group.

Creating and managing groups on HP-UX

On HP-UX, providing you are not using NIS or NIS+, use the System Administration Manager (SAM) to work with groups.

Creating a group on HP-UX

Add a user to a group by using the System Administration Manager

Procedure

1. From the System Administration Manager (SAM), double click Accounts for Users and Groups.
2. Double click Groups.
3. Select Add from the Actions pull down to display the Add a New Group panel.
4. Enter the name of the group and select the users that you want to add to the group.
5. Click Apply to create the group.

Results

You have now created a group.

Adding a user to a group on HP-UX

Add a user to a group by using the System Administration Manager.

Procedure

1. From the System Administration Manager (SAM), double click Accounts for Users and Groups.
2. Double click Groups.
3. Highlight the name of the group and select Modify from the Actions pull down to display the Modify an Existing Group panel.
4. Select a user that you want to add to the group and click Add.
5. If you want to add other users to the group, repeat step 4 for each user.
6. When you have finished adding names to the list, click OK.

Results

You have now added a user to a group.

Displaying who is in a group on HP-UX

Display who is in a group by using the System Administration Manager

Procedure

1. From the System Administration Manager (SAM), double click Accounts for Users and Groups.
2. Double click Groups.
3. Highlight the name of the group and select Modify from the Actions pull down to display the Modify an Existing Group panel, showing a list of the users in the group.

Results

The group members are displayed.

Removing a user from a group on HP-UX

Remove a user from a group by using the System Administration Manager.

Procedure

1. From the System Administration Manager (SAM), double click Accounts for Users and Groups.
2. Double click Groups.
3. Highlight the name of the group and select Modify from the Actions pull down to display the Modify an Existing Group panel.
4. Select a user that you want to remove from the group and click Remove.
5. If you want to remove other users from the group, repeat step 4 for each user.
6. When you have finished removing names from the list, click OK.

Results

You have now removed a user from a group

Creating and managing groups on AIX

On AIX, providing you are not using NIS or NIS+, use SMITTY to work with groups.

Creating a group

Create a group using SMITTY.

Procedure

1. From SMITTY, select Security and Users and press Enter.
2. Select Groups and press Enter.
3. Select Add a Group and press Enter.
4. Enter the name of the group and the names of any users that you want to add to the group, separated by commas.
5. Press Enter to create the group.

Results

You have now created a group.

Adding a user to a group

Add a user to a group by using SMITTY.

Procedure

1. From SMITTY, select Security and Users and press Enter.
2. Select Groups and press Enter.
3. Select Change / Show Characteristics of Groups and press Enter.
4. Enter the name of the group to show a list of the members of the group.
5. Add the names of the users that you want to add to the group, separated by commas.
6. Press Enter to add the names to the group.

Displaying who is in a group

Display who is in a group using SMITTY.

Procedure

1. From SMITTY, select Security and Users and press Enter.
2. Select Groups and press Enter.
3. Select Change / Show Characteristics of Groups and press Enter.
4. Enter the name of the group to show a list of the members of the group.

Results

The group members are displayed.

Removing a user from a group

Remove a user from a group by using SMITTY.

Procedure

1. From SMITTY, select Security and Users and press Enter.
2. Select Groups and press Enter.
3. Select Change / Show Characteristics of Groups and press Enter.
4. Enter the name of the group to show a list of the members of the group.
5. Delete the names of the users that you want to remove from the group.
6. Press Enter to remove the names from the group.

Results

You have now removed a user from a group.

Creating and managing groups on Solaris

On Solaris, providing you are not using NIS or NIS+, use the `/etc/group` file to work with groups.

Creating a group on Solaris

Creating a group by using the **`groupadd`** command.

Procedure

Type the following command: `groupadd` *`group-name`* where *group-name* is the name of the group.

Results

The file `/etc/group` file holds group information.

Adding a user to a group on Solaris

Add a user to a group by using the **`usermod`** command.

Procedure

To add a member to a supplementary group, execute the `usermod` command and list the supplementary groups that the user is currently a member of, and the supplementary groups that the user is to become a member of. For example, if the user is a member of the group `groupa`, and is to become a member of `groupb` also, use the following command: `usermod -G groupa,groupb` *`user-name`*, where *user-name* is the user name.

Displaying who is in a group on Solaris

To discover who is a member of a group, look at the entry for that group in the `/etc/group` file.

Removing a user from a group on Solaris

Remove a user from a group by using the **`usermod`** command.

Procedure

To remove a member from a supplementary group, execute the **`usermod`** command listing the supplementary groups that you want the user to remain a member of. For example, if the user's primary group is `users` and the user is also a member of the groups `mqm`, `groupa` and `groupb`, to remove the user from the `mqm` group, the following command is used: `usermod -G groupa,groupb` *`user-name`*, where *`user-name`* is the user name.

Creating and managing groups on Linux

On Linux, providing you are not using NIS or NIS+, use the `/etc/group` file to work with groups.

Creating a group on Linux

Create a group by using the **groupadd** command.

Procedure

To create a new group, type the following command: `groupadd -g` *group-ID group-name* , where *group-ID* is the numeric identifier of the group, and *group-name* is the name of the group.

Results

The file `/etc/group` file holds group information.

Adding a user to a group on Linux

Add a user to a group by using the **usermod** command.

Procedure

To add a member to a supplementary group, execute the `usermod` command and list the supplementary groups that the user is currently a member of, and the supplementary groups that the user is to become a member of. For example, if the user is a member of the group `groupa`, and is to become a member of `groupb` also, the following command is used: `usermod -G groupa,groupb` *user-name* , where *user-name* is the user name.

Displaying who is in a group on Linux

Display who is in a group by using the **getent** command.

Procedure

To display who is a member of a group, type the following command: `getent group` *group-name* , where *group-name* is the name of the group.

Removing a user from a group

Remove a user from a group by using the **usermod** command.

Procedure

To remove a member from a supplementary group, execute the **usermod** command listing the supplementary groups that you want the user to remain a member of. For example, if the user's primary group is `users` and the user is also a member of the groups `mqm`, `groupa` and `groupb`, to remove the user from the `mqm` group, the following command is used: `usermod -G groupa,groupb` *user-name* , where *user-name* is the user name.

How authorizations work

The authorization specification tables in the topics in this section define precisely how the authorizations work and the restrictions that apply.

The tables apply to these situations:

- Applications that issue MQI calls
- Administration programs that issue MQSC commands as escape PCFs
- Administration programs that issue PCF commands

In this section, the information is presented as a set of tables that specify the following:

Action to be performed
MQI option, MQSC command, or PCF command.

Access control object
Queue, process, queue manager, namelist, authentication information, channel, client connection channel, listener, or service.

Authorization required
Expressed as an MQZAO_ constant.

In the tables, the constants prefixed by MQZAO_ correspond to the keywords in the authorization list for the **setmqaut** command for the particular entity. For example, MQZAO_BROWSE corresponds to the keyword `+browse`, MQZAO_SET_ALL_CONTEXT corresponds to the keyword `+setall`, and so on. These constants are defined in the header file cmqzc.h, supplied with the product.

Authorizations for MQI calls

MQCONN, **MQOPEN**, **MQPUT1**, and **MQCLOSE** might require authorization checks. The tables in this topic summarize the authorizations needed for each call.

An application is allowed to issue specific MQI calls and options only if the user identifier under which it is running (or whose authorizations it is able to assume) has been granted the relevant authorization.

Four MQI calls might require authorization checks: **MQCONN**, **MQOPEN**, **MQPUT1**, and **MQCLOSE**.

For **MQOPEN** and **MQPUT1** , the authority check is made on the name of the object being opened, and not on the name, or names, resulting after a name has been resolved. For example, an application might be granted authority to open an alias queue without having authority to open the base queue to which the alias resolves. The rule is that the check is carried out on the first definition encountered during the process of resolving a name that is not a queue manager alias, unless the queue manager alias definition is opened directly; that is, its name is displayed in the *ObjectName* field of the object descriptor. Authority is always needed for the object being opened. In some cases additional queue-independent authority, obtained through an authorization for the queue manager object, is required.

Table 23 on page 520, Table 24 on page 520, Table 25 on page 521, and Table 26 on page 521 summarize the authorizations needed for each call. In the tables *Not applicable* means that authorization checking is not relevant to this operation; *No check* means that no authorization checking is performed.

Note: You will find no mention of namelists, channels, client connection channels, listeners, services, or authentication information objects in these tables. This is because none of the authorizations apply to these objects, except for MQOO_INQUIRE, for which the same authorizations apply as for the other objects.

The special authorization MQZAO_ALL_MQI includes all the authorizations in the tables that are relevant to the object type, except MQZAO_DELETE and MQZAO_DISPLAY, which are classed as administration authorizations.

In order to modify any of the message context options, you must have the appropriate authorizations to issue the call. For example, in order to use MQOO_SET_IDENTITY_CONTEXT or MQPMO_SET_IDENTITY_CONTEXT, you must have `+setid` permission.

Table 23. Security authorization needed for MQCONN calls

Authorization required for:	**Queue object (1 on page 521)**	**Process object**	**Queue manager object**
MQCONN	Not applicable	Not applicable	MQZAO_CONNECT

Table 24. Security authorization needed for MQOPEN calls

Authorization required for:	**Queue object (1 on page 521)**	**Process object**	**Queue manager object**
MQOO_INQUIRE	MQZAO_INQUIRE	MQZAO_INQUIRE	MQZAO_INQUIRE
MQOO_BROWSE	MQZAO_BROWSE	Not applicable	No check
MQOO_INPUT_*	MQZAO_INPUT	Not applicable	No check
MQOO_SAVE_ ALL_CONTEXT **(2 on page 521)**	MQZAO_INPUT	Not applicable	Not applicable
MQOO_OUTPUT (Normal queue) **(3 on page 521)**	MQZAO_OUTPUT	Not applicable	Not applicable
MQOO_PASS_ IDENTITY_CONTEXT **(4 on page 521)**	MQZAO_PASS_ IDENTITY_CONTEXT	Not applicable	No check
MQOO_PASS_ALL_ CONTEXT **(4 on page 521, 5 on page 521)**	MQZAO_PASS _ALL_CONTEXT	Not applicable	No check
MQOO_SET_ IDENTITY_CONTEXT **(4 on page 521, 5 on page 521)**	MQZAO_SET_ IDENTITY_CONTEXT	Not applicable	MQZAO_SET_ IDENTITY_CONTEXT **(6 on page 521)**
MQOO_SET_ ALL_CONTEXT **(4 on page 521, 7 on page 521)**	MQZAO_SET_ ALL_CONTEXT	Not applicable	MQZAO_SET_ ALL_CONTEXT **(6 on page 521)**
MQOO_OUTPUT (Transmission queue) **(8 on page 521)**	MQZAO_SET_ ALL_CONTEXT	Not applicable	MQZAO_SET_ ALL_CONTEXT **(6 on page 521)**
MQOO_SET	MQZAO_SET	Not applicable	No check
MQOO_ALTERNATE_ USER_AUTHORITY	**(9 on page 521)**	**(9 on page 521)**	MQZAO_ALTERNATE_ USER_AUTHORITY **(9 on page 521, 10 on page 522)**

Table 25. Security authorization needed for MQPUT1 calls

Authorization required for:	**Queue object (1)**	**Process object**	**Queue manager object**
MQPMO_PASS_ IDENTITY_CONTEXT	MQZAO_PASS_ IDENTITY_CONTEXT **(11 on page 522)**	Not applicable	No check
MQPMO_PASS_ALL _CONTEXT	MQZAO_PASS_ ALL_CONTEXT **(11 on page 522)**	Not applicable	No check
MQPMO_SET_ IDENTITY_CONTEXT	MQZAO_SET_ IDENTITY_CONTEXT **(11 on page 522)**	Not applicable	MQZAO_SET_ IDENTITY_CONTEXT **(6)**
MQPMO_SET_ ALL_CONTEXT	MQZAO_SET_ ALL_CONTEXT **(11 on page 522)**	Not applicable	MQZAO_SET_ ALL_CONTEXT **(6)**
(Transmission queue) **(8)**	MQZAO_SET_ ALL_CONTEXT	Not applicable	MQZAO_SET_ ALL_CONTEXT **(6)**
MQPMO_ALTERNATE_ USER_AUTHORITY	**(12 on page 522)**	Not applicable	MQZAO_ALTERNATE_ USER_AUTHORITY **(10 on page 522)**

Table 26. Security authorization needed for MQCLOSE calls

Authorization required for:	**Queue object (1)**	**Process object**	**Queue manager object**
MQCO_DELETE	MQZAO_DELETE **(13 on page 522)**	Not applicable	Not applicable
MQCO_DELETE _PURGE	MQZAO_DELETE **(13 on page 522)**	Not applicable	Not applicable

Notes for the tables:

1. If opening a model queue:
   - MQZAO_DISPLAY authority is needed for the model queue, in addition to the authority to open the model queue for the type of access for which you are opening.
   - MQZAO_CREATE authority is not needed to create the dynamic queue.
   - The user identifier used to open the model queue is automatically granted all the queue-specific authorities (equivalent to MQZAO_ALL) for the dynamic queue created.
2. MQOO_INPUT_* must also be specified. This is valid for a local, model, or alias queue.
3. This check is performed for all output cases, except transmission queues (see note 8).
4. MQOO_OUTPUT must also be specified.
5. MQOO_PASS_IDENTITY_CONTEXT is also implied by this option.
6. This authority is required for both the queue manager object and the particular queue.
7. MQOO_PASS_IDENTITY_CONTEXT, MQOO_PASS_ALL_CONTEXT, and MQOO_SET_IDENTITY_CONTEXT are also implied by this option.
8. This check is performed for a local or model queue that has a *Usage* queue attribute of MQUS_TRANSMISSION, and is being opened directly for output. It does not apply if a remote queue is being opened (either by specifying the names of the remote queue manager and remote queue, or by specifying the name of a local definition of the remote queue).
9. At least one of MQOO_INQUIRE (for any object type), or MQOO_BROWSE, MQOO_INPUT_*, MQOO_OUTPUT, or MQOO_SET (for queues) must also be specified. The check carried out is as for the other options specified, using the supplied alternate-user identifier for the specific-named object authority, and the current application authority for the MQZAO_ALTERNATE_USER_IDENTIFIER check.

10. This authorization allows any *AlternateUserId* to be specified.
11. An MQZAO_OUTPUT check is also carried out if the queue does not have a *Usage* queue attribute of MQUS_TRANSMISSION.
12. The check carried out is as for the other options specified, using the supplied alternate-user identifier for the specific-named queue authority, and the current application authority for the MQZAO_ALTERNATE_USER_IDENTIFIER check.
13. The check is carried out only if both of the following are true:
    - A permanent dynamic queue is being closed and deleted.
    - The queue was not created by the **MQOPEN** call that returned the object handle being used.

    Otherwise, there is no check.

Authorizations for MQSC commands in escape PCFs

This information summarizes the authorizations needed for each MQSC command contained in Escape PCF.

Not applicable means that this operation is not relevant to this object type.

The user ID under which the program that submits the command is running must also have the following authorities:
- MQZAO_CONNECT authority to the queue manager
- MQZAO_DISPLAY authority on the queue manager in order to perform PCF commands
- Authority to issue the MQSC command within the text of the Escape PCF command

`ALTER object`

Command	Object	Authorization required
DISPLAY CHSTATUS	Queue manager	MQZAO_DISPLAY Note that `+inq` authority (or equivalently MQZAO_INQUIRE) is required on the transmission queue if the channel type is CLUSSDR.
DISPLAY LSSTATUS	Queue manager	MQZAO_DISPLAY
DISPLAY PUBSUB	Queue manager	MQZAO_DISPLAY
DISPLAY SBSTATUS	Queue manager	MQZAO_DISPLAY
DISPLAY SVSTATUS	Queue manager	MQZAO_DISPLAY
DISPLAY TPSTATUS	Queue manager	MQZAO_DISPLAY

Cluster Commands

Command	Object	Authorization required
DISPLAY CLUSQMGR	Queue manager	MQZAO_DISPLAY
REFRESH CLUSTER	'mqm' group membership required	
RESET CLUSTER	'mqm' group membership required	
SUSPEND QMGR	'mqm' group membership required	
RESUME QMGR	'mqm' group membership required	

Other Administrative Commands

Command	Object	Authorization required
PING QMGR	Queue manager	MQZAO_DISPLAY
REFRESH QMGR	Queue manager	MQZAO_CHANGE
RESET QMGR	Queue manager	MQZAO_CHANGE
DISPLAY CONN	Queue manager	MQZAO_DISPLAY
STOP CONN	Queue manager	MQZAO_CHANGE

Note:

1. For DEFINE commands, MQZAO_DISPLAY authority is also needed for the LIKE object if one is specified, or on the appropriate SYSTEM.DEFAULT.xxx object if LIKE is omitted.
2. The MQZAO_CREATE authority is not specific to a particular object or object type. Create authority is granted for all objects for a specified queue manager, by specifying an object type of QMGR on the **setmqaut** command.
3. This applies if the object to be replaced already exists. If it does not, the check is as for DEFINE *object* NOREPLACE.

Clustering: Using REFRESH CLUSTER best practices

Authorizations for PCF commands

This section summarizes the authorizations needed for each PCF command.

No check means that no authorization checking is carried out; *Not applicable* means that this operation is not relevant to this object type.

The user ID under which the program that submits the command is running must also have the following authorities:

- MQZAO_CONNECT authority to the queue manager
- MQZAO_DISPLAY authority on the queue manager in order to perform PCF commands

The special authorization MQZAO_ALL_ADMIN includes all the authorizations in the following list that are relevant to the object type, except MQZAO_CREATE, which is not specific to a particular object or object type.

Channel	MQZAO_CONTROL
Client connection channel	Not applicable
Listener	MQZAO_CONTROL
Service	MQZAO_CONTROL
Communication information	Not applicable

Channel Commands

Command	Object	Authorization required
Ping Channel	Channel	MQZAO_CONTROL
Reset Channel	Channel	MQZAO_CONTROL_EXTENDED
Resolve Channel	Channel	MQZAO_CONTROL_EXTENDED

Subscription Commands

Command	Object	Authorization required
Change Subscription	Topic	MQZAO_CONTROL
Create Subscription	Topic	MQZAO_CONTROL
Delete Subscription	Topic	MQZAO_CONTROL
Inquire Subscription	Topic	MQZAO_DISPLAY

Security Commands

Command	Object	Authorization required
Set Authority Record	Queue manager	MQZAO_CHANGE
Delete Authority Record	Queue manager	MQZAO_CHANGE
Inquire Authority Records	Queue manager	MQZAO_DISPLAY
Inquire Authority Service	Queue manager	MQZAO_DISPLAY
Inquire Entity Authority	Queue manager	MQZAO_DISPLAY
Set Channel Authentication Record	Queue manager	MQZAO_CHANGE
Inquire Channel Authentication Records	Queue manager	MQZAO_DISPLAY
Refresh Security	Queue manager	MQZAO_CHANGE

Status Displays

Command	Object	Authorization required
Inquire Channel Status	Queue manager	MQZAO_DISPLAY Note that `+inq` authority (or equivalently MQZAO_INQUIRE) is required on the transmission queue if the channel type is CLUSSDR.
Inquire Channel Listener Status	Queue manager	MQZAO_DISPLAY
Inquire Pub/Sub Status	Queue manager	MQZAO_DISPLAY
Inquire Subscription Status	Queue manager	MQZAO_DISPLAY
Inquire Service Status	Queue manager	MQZAO_DISPLAY
Inquire Topic Status	Queue manager	MQZAO_DISPLAY

Cluster Commands

Command	Object	Authorization required
Inquire Cluster Queue Manager	Queue manager	MQZAO_DISPLAY
Refresh Cluster	'mqm' group membership required	'mqm' group membership required
Reset Cluster	'mqm' group membership required	'mqm' group membership required
Suspend Queue Manager Cluster	'mqm' group membership required	'mqm' group membership required
Resume Queue Manager Cluster	'mqm' group membership required	'mqm' group membership required

Other Administrative Commands

Command	Object	Authorization required
Ping Queue Manager	Queue manager	MQZAO_DISPLAY
Refresh Queue Manager	Queue manager	MQZAO_CHANGE
Reset Queue Manager	Queue manager	MQZAO_CHANGE
Reset Queue Statistics	Queue	MQZAO_DISPLAY and MQZAO_CHANGE
Inquire Connection	Queue manager	MQZAO_DISPLAY
Stop Connection	Queue manager	MQZAO_CHANGE

Note:
1. For Copy commands, MQZAO_DISPLAY authority is also needed for the From object.
2. The MQZAO_CREATE authority is not specific to a particular object or object type. Create authority is granted for all objects for a specified queue manager, by specifying an object type of QMGR on the **setmqaut** command.
3. For Create commands, MQZAO_DISPLAY authority is also needed for the appropriate SYSTEM.DEFAULT.* object.
4. This applies if the object to be replaced already exists. If it does not, the check is as for Copy or Create without replace.

Special considerations for security on Windows

Some security functions behave differently on different versions of Windows.

IBM MQ security relies on calls to the operating system API for information about user authorizations and group memberships. Some functions do not behave identically on the Windows systems. This collection of topics includes descriptions of how those differences might affect IBM MQ security when you are running IBM MQ in a Windows environment.

The SSPI channel exit program

IBM MQ for Windows supplies a security exit program, which can be used on both message and MQI channels. The exit is supplied as source and object code, and provides one-way and two-way authentication.

The security exit uses the Security Support Provider Interface (SSPI), which provides the integrated security facilities of Windows platforms.

The security exit provides the following identification and authentication services:

One way authentication

This uses Windows NT LAN Manager (NTLM) authentication support. NTLM allows servers to authenticate their clients. It does not allow a client to authenticate a server, or one server to authenticate another. NTLM was designed for a network environment in which servers are assumed to be genuine. NTLM is supported on all Windows platforms that are supported by IBM WebSphere MQ Version 7.0.

This service is typically used on an MQI channel to enable a server queue manager to authenticate an IBM MQ MQI client application. A client application is identified by the user ID associated with the process that is running.

To perform the authentication, the security exit at the client end of a channel acquires an authentication token from NTLM and sends the token in a security message to its partner at the other end of the channel. The partner security exit passes the token to NTLM, which checks that the token is authentic. If the partner security exit is not satisfied with the authenticity of the token, it instructs the MCA to close the channel.

Two way, or mutual, authentication

This uses Kerberos authentication services. The Kerberos protocol does not assume that servers in a network environment are genuine. Servers can authenticate clients and other servers, and clients can authenticate servers. Kerberos is supported on all Windows platforms that are supported by IBM WebSphere MQ Version 7.0.

This service can be used on both message and MQI channels. On a message channel, it provides mutual authentication of the two queue managers. On an MQI channel, it enables the server queue manager and the IBM MQ MQI client application to authenticate each other. A queue manager is identified by its name prefixed by the string `ibmMQSeries/`. A client application is identified by the user ID associated with the process that is running.

To perform the mutual authentication, the initiating security exit acquires an authentication token from the Kerberos security server and sends the token in a security message to its partner. The partner security exit passes the token to the Kerberos server, which checks that it is authentic. The Kerberos security server generates a second token, which the partner sends in a security message to the initiating security exit. The initiating security exit then asks the Kerberos server to check that the second token is authentic. During this exchange, if either security exit is not satisfied with the authenticity of the token sent by the other, it instructs the MCA to close the channel.

The security exit is supplied in both source and object format. You can use the source code as a starting point for writing your own channel exit programs or you can use the object module as supplied. The object module has two entry points, one for one way authentication using NTLM authentication support and the other for two way authentication using Kerberos authentication services.

For more information about how the SSPI channel exit program works, and for instructions on how to implement it, see Using the SSPI security exit on Windows systems.

When you get a 'group not found' error on Windows

This problem can arise because IBM MQ loses access to the local mqm group when Windows servers are promoted to, or demoted from, domain controllers. To remedy this problem, re-create the local mqm group.

The symptom is an error indicating the lack of a local mqm group, for example:

```
>crtmqm qm0
AMQ8066:Local mqm group not found.
```

Altering the state of a machine between server and domain controller can affect the operation of IBM MQ, because IBM MQ uses a locally-defined mqm group. When a server is promoted to be a domain controller, the scope changes from local to domain local. When the machine is demoted to server, all domain local groups are removed. This means that changing a machine from server to domain controller and back to server loses access to a local mqm group.

To remedy this problem, re-create the local mqm group using the standard Windows management tools. Because all group membership information is lost, you must reinstate privileged IBM MQ users in the newly-created local mqm group. If the machine is a domain member, you must also add the domain mqm group to the local mqm group to grant privileged domain IBM MQ user IDs the required level of authority.

When you have problems with IBM MQ and domain controllers on Windows

Certain problems can arise with security settings when Windows servers are promoted to domain controllers.

While promoting Windows 2000, Windows 2003, or Windows Server 2008 servers to domain controllers, you are presented with the option of selecting a default or non-default security setting relating to user and group permissions. This option controls whether arbitrary users are able to retrieve group memberships from the active directory. Because IBM MQ relies on group membership information to implement its security policy, it is important that the user ID that is performing IBM MQ operations can determine the group memberships of other users.

On Windows 2000, when a domain is created using the default security option, the default user ID created by IBM MQ during the installation process can obtain group memberships for other users as required. The product then installs normally, creating default objects, and the queue manager can determine the access authority of local and domain users if required.

On Windows 2000, when a domain is created using the non-default security option, or on Windows 2003 and Windows Server 2008 when a domain is created using the default security option, the user ID created by IBM MQ during the installation cannot always determine the required group memberships. In this case, you need to know:

- How Windows 2000 with non-default, or Windows 2003 and Windows Server 2008 with default, security permissions behaves
- How to allow domain mqm group members to read group membership
- How to configure an IBM MQ Windows service to run under a domain user

Windows Server 2008 and Windows Server 2012 domain with default, security permissions:

Installation of IBM MQ behaves differently on these operating systems depending on whether a local user or domain user performs the installation.

If a **local** user installs IBM MQ, the Prepare IBM MQ Wizard detects that the local user created for the IBM MQ Windows service can retrieve the group membership information of the installing user. The Prepare IBM MQ Wizard asks the user questions about the network configuration to determine whether there are other user accounts defined on domain controllers running on Windows 2000 or later. If so, the IBM MQ Windows service needs to run under a domain user account with particular settings and authorities. The Prepare IBM MQ Wizard prompts the user for the account details of this user. Its online help provides details of the domain user account required that can be sent to the domain administrator.

If a **domain** user installs IBM MQ, the Prepare IBM MQ Wizard detects that the local user created for the IBM MQ Windows service cannot retrieve the group membership information of the installing user. In this case, the Prepare IBM MQ Wizard always prompts the user for the account details of the domain user account for the IBM MQ Windows service to use.

When the IBM MQ Windows service needs to use a domain user account, IBM MQ cannot operate correctly until this has been configured using the Prepare IBM MQ Wizard. The Prepare IBM MQ Wizard does not allow the user to continue with other tasks, until the Windows service has been configured with a suitable account.

See Creating and setting up domain accounts for IBM MQ for more information.

Configuring IBM MQ Services to run under a domain user on Windows:

Use the Prepare IBM MQ wizard to enter the account details of the domain user account. Alternatively, you can use the Computer Management panel to alter the **Log On** details for the installation specific IBM MQ Service.

For more information see Changing the password of the IBM MQ Windows service user account

Applying security template files to Windows

Applying a template might affect the security settings applied to IBM MQ files and directories. If you use the highly secure template, apply it before installing IBM MQ.

Windows supports text-based security template files that you can use to apply uniform security settings to one or more computers with the Security Configuration and Analysis MMC snap-in. In particular, Windows supplies several templates that include a range of security settings with the aim of providing specific levels of security. These templates include Compatible, Secure, and Highly Secure.

Applying one of these templates might affect the security settings applied to IBM MQ files and directories. If you want to use the Highly Secure template, configure your machine before you install IBM MQ.

If you apply the highly secure template to a machine on which IBM MQ is already installed, all the permissions you have set on the IBM MQ files and directories are removed. Because these permissions are removed, you lose *Administrator*, *mqm*, and, when applicable, *Everyone* group access from the error directories.

Nested groups

There are restrictions on the use of nested groups. These result partly from the domain functional level and partly from IBM MQ restrictions.

Active Directory can support different group types within a Domain context depending on the Domain functional level. By default, Windows 2003 domains are in the " Windows 2000 mixed" functional level. (Windows Server 2008 and Windows Server 2012 follow the Windows 2003 domain model.) The domain functional level determines the supported group types and level of nesting allowed when configuring user IDs in a domain environment. Refer to Active Directory documentation for details on the Group Scope and inclusion criteria.

In addition to Active Directory requirements, further restrictions are imposed on IDs used by IBM MQ. The network APIs used by IBM MQ do not support all the configurations that are supported by the domain functional level. As a result, IBM MQ is not able to query the group memberships of any Domain IDs present in a Domain Local group which is then nested in a local group. Furthermore, multiple nesting of global and universal groups is not supported. However, immediately nested global or universal groups are supported.

Configuring additional authority for Windows applications connecting to IBM MQ

The account under which IBM MQ processes run might need additional authorization before SYNCHRONIZE access to application processes can be granted.

You might experience problems if you have Windows applications, for example ASP pages, connecting to IBM MQ that are configured to run at a security level higher than usual.

IBM MQ requires SYNCHRONIZE access to application processes in order to coordinate certain actions. APAR IC35116 changed IBM MQ so that the appropriate privileges are specified. However, the account under which IBM MQ processes run might need additional authorization before the requested access can be granted.

When a server application first attempts to connect to a queue manager IBM MQ will modify the process to grant SYNCHRONIZE authority for IBM MQ administrators. To configure additional authority to the user ID under which IBM MQ processes are running, complete the following steps:

1. Start the Local Security Policy tool, click Security Settings ->Local Policies->User Right Assignments, click "Debug Programs".
2. Double click "Debug Programs", then add your IBM MQ user ID to the list

If the system is in a Windows domain and the effective policy setting is still not set, even though the local policy setting is set, the user ID must be authorized in the same way at domain level, using the Domain Security Policy tool.

Setting up security on HP Integrity NonStop Server

Security considerations specific to HP Integrity NonStop Server systems.

The IBM MQ client for HP Integrity NonStop Server supports both the Transport Layer Security (TLS) and the Secure Sockets Layer (SSL) protocols to provide link level security when you are connecting to a queue manager. These protocols are supported by using an implementation of OpenSSL. OpenSSL requires a source of random data for providing strong cryptographic operations.

OpenSSL

OpenSSL security overview for IBM MQ client for HP Integrity NonStop Server.

The OpenSSL toolkit is an open source implementation of the Secure Sockets Layer (SSL) and Transport Layer Security (TLS) protocols for secure communications over a network.

The toolkit is developed by the OpenSSL Project. For more information about the OpenSSL Project, see http://www.openssl.org. IBM MQ client for HP Integrity NonStop Server contains modified versions of the OpenSSL libraries and the **openssl** command. The libraries and **openssl** command are ported from the OpenSSL toolkit 1.0.1c, and are supplied as object code only. No source code is provided.

The OpenSSL libraries are loaded by IBM MQ client application programs dynamically as required. Only the OpenSSL libraries that are provided by IBM MQ are supported for use with IBM MQ client applications.

The **openssl** command, which can be used for certificate management purposes, is installed in the OSS directory `opt_installation_path/opt/mqm/bin`.

Using the **openssl** command, you can create and manage keys and digital certificates with various common data formats, and carry out simple certificate authority (CA) tasks.

The default format for key and certificate data that is processed by OpenSSL is the Privacy Enhanced Mail (PEM) format. Data in PEM format is base64 encoded ASCII data. The data can therefore be transferred by using text-based systems such as email, and can be cut and pasted by using text editors and web browsers. PEM is an Internet standard for text-based cryptographic exchanges and is specified in Internet RFCs 1421, 1422, 1423, and 1424. IBM MQ assumes that a file with extension `.pem` contains data in PEM format. A file in PEM format can contain multiple certificates and other encoded objects, and can include comments.

The IBM MQ SSL support on other operating systems might require key and certificate data in files to be encoded by using Distinguished Encoding Rules (DER). DER is a set of encoding rules for using the ASN.1 notation in secure communications. Data that is encoded by using DER is binary data, and the format of key and certificate data that is encoded by using DER is also known as PKCS#12 or PFX. A file that contains this data commonly has an extension of `.p12` or `.pfx`. The **openssl** command can convert between PEM and PKCS#12 format.

Entropy Daemon

OpenSSL requires a source of random data for providing strong cryptographic operations. Random number generation is a capability that is usually provided by the operating system or by a system-wide daemon process. The HP Integrity NonStop Server operating system does not provide this capability within the operating system.

When you are using the SSL and TLS support supplied with IBM MQ client for HP Integrity NonStop Server, a process that is called an entropy daemon is needed to provide the source of random data. When you start a client channel that requires SSL or TLS, OpenSSL expects an entropy daemon to be running and providing its services on a socket in the OSS file system at `/etc/egd-pool`.

An entropy daemon is not provided by IBM MQ client for HP Integrity NonStop Server. The IBM MQ client for HP Integrity NonStop Server is tested with the following entropy daemons:

- amqjkdm0 (as provided by the IBM MQ 5.3 server)
- `/usr/local/bin/prngd` (Version 0.9.27, as provided by HP Integrity NonStop Server Open Source Technical Library)

Setting up security on IBM i

Security for IBM MQ for IBM i is implemented using the IBM MQ Object Authority Manager (OAM) and IBM i object level security.

Security considerations that must be made when determining access authority to IBM MQ objects.

You need to consider the following points when setting up authorities to the users in your enterprise:

1. Grant and revoke authorities to the IBM MQ for IBM i commands using the IBM i **GRTOBJAUT** and **RVKOBJAUT** commands.

   In the `QMQM` library, certain noncommand (*cmd) objects are set to have **`*PUBLIC`** authority to **`*USE`**. Do not change the authorities of these objects or use an authorization list to provide authority. Any incorrect authority might compromise IBM MQ functionality.
2. During installation of IBM MQ for IBM i, the following special user profiles are created:

   QMQM
   : Is used primarily for internal product-only functions. However, it can be used to run trusted applications using MQCNO_FASTPATH_BINDINGS. See Connecting to a queue manager using the MQCONNX call.

   QMQMADM
   : Is used as a group profile for administrators of IBM MQ. The group profile gives access to CL commands and IBM MQ resources.

   When using SBMJOB to submit programs that call IBM MQ commands, USER must not be set explicitly to QMQMADM. Instead, set USER to QMQM or another user profile that has QMQMADM specified as a group.
3. If you are sending channel commands to remote queue managers, ensure that your user profile is a member of the group QMQMADM on the target system. For a list of PCF and MQSC channel commands, see IBM MQ for IBM i CL commands.
4. The group set associated with a user is cached when the group authorizations are computed by the OAM.

   Any changes made to a user's group memberships after the group set has been cached are not recognized until you restart the queue manager or execute RFRMQMAUT to refresh security.
5. Limit the number of users who have authority to work with commands that are particularly sensitive. These commands include:
   - Create Message Queue Manager (**CRTMQM**)

- Delete Message Queue Manager (**DLTMQM**)
- Start Message Queue Manager (**STRMQM**)
- End Message Queue Manager (**ENDMQM**)
- Start Command Server (**STRMQMCSVR**)
- End Command Server (**ENDMQMCSVR**)

6. Channel definitions contain a security exit program specification. Channel creation and modification requires special considerations. Details of security exits are given in “Security exit overview” on page 477.
7. The channel exit and trigger monitor programs can be substituted. The security of such replacements is the responsibility of the programmer.

The object authority manager on IBM i

The object authority manager (OAM) manages users' authorizations to manipulate IBM MQ objects, including queues and process definitions. It also provides a command interface through which you can grant or revoke access authority to an object for a specific group of users. The decision to allow access to a resource is made by the OAM, and the queue manager follows that decision. If the OAM cannot make a decision, the queue manager prevents access to that resource.

Through the OAM you can control:

- Access to IBM MQ objects through the MQI. When an application program attempts to access an object, the OAM checks that the user profile making the request has the authorization for the operation requested.

  In particular, this means that queues, and the messages on queues, can be protected from unauthorized access.
- Permission to use PCF and MQSC commands.

Different groups of users can have different access authority to the same object. For example, for a specific queue, one group could perform both put and get operations; another group might be allowed only to browse the queue (MQGET with browse option). Similarly, some groups might have get and put authority to a queue, but not be allowed to alter or delete the queue.

IBM MQ for IBM i commands and perform operations on IBM MQ for IBM i objects

IBM MQ authorities on IBM i

To access IBM MQ objects, you need authority to issue the command and to access the object referenced. Administrators have access to all IBM MQ resources.

Access to IBM MQ objects is controlled by authorities to:

1. Issue the IBM MQ command
2. Access the IBM MQ objects referenced by the command

All IBM MQ for IBM i CL commands are shipped with an owner of QMQM, and the administration profile (QMQMADM) has *USE rights with the *PUBLIC access set to *EXCLUDE.

Note: The QSRDUPER program is used by the IBM MQ for IBM i licensed program install to duplicate Command (*CMD) objects in QSYS. In IBM i V5R4 and later, the QSRDUPER program was changed so that the default behavior is to create a proxy command rather than a duplicate of the original command. A proxy command redirects command execution to another command and has an attribute of PRX. If a proxy command by the same name as the command being copied exists in library QSYS, private authorities to the proxy command are not granted to the command in the product library. Attempts to prompt or run the proxy command in QSYS check the authority of the target command in the product library. Any changes in authority to *CMD objects therefore need to be done in the product library (QMQM) and those in QSYS do not need to be modified. For example:

```
GRTOBJAUT OBJ(QMQM/DSPMQMQ) OBJTYPE(*CMD) USER(MQUSER) AUT(*USE)
```

Changes to the authority structure of some of the product's CL commands allows public use of these commands, if you have the required OAM authority to the IBM MQ objects to make these changes.

To be an IBM MQ administrator on IBM i, you must be a member of the *QMQMADM group*. This group has properties like the properties of the mqm group on UNIX, Linux and Windows systems. In particular, the QMQMADM group is created when you install IBM MQ for IBM i, and members of the QMQMADM group have access to all IBM MQ resources on the system. You also have access to all IBM MQ resources if you have *ALLOBJ authority.

Administrators can use CL commands to administer IBM MQ. One of these commands is GRTMQMAUT, which is used to grant authorities to other users. Another command, STRMQMMQSC, enables an administrator to issue MQSC commands to a local queue manager.

Related concepts:

"Authority to administer IBM MQ on IBM i" on page 449

Access authorities for IBM MQ objects on IBM i

Access authorities required for running IBM MQ CL commands.

IBM MQ for IBM i categorizes the product's CL commands into two groups:

Group 1

Users must be in the QMQMADM user group, or have *ALLOBJ authority, to process these commands. Users having either of these authorities can process all commands in all categories without requiring any extra authority.

Note: These authorities override any OAM authority.

These commands can be grouped as follows:

- Command Server Commands
  - ENDMQMCSVR, End IBM MQ Command Server
  - STRMQMCSVR, Start IBM MQ Command Server
- Dead-Letter Queue Handler Command
  - STRMQMDLQ, Start IBM MQ Dead-Letter Queue Handler
- Listener Command
  - ENDMQMLSR, End IBM MQ listener
  - STRMQMLSR, Start non-object listener
- Media Recovery Commands
  - RCDMQMIMG, Record IBM MQ Object Image
  - RCRMQMOBJ, Re-create IBM MQ Object
  - WRKMQMTRN, Work with IBM MQ Q Transactions
- Queue Manager Commands
  - CRTMQM, Create Message Queue Manager
  - DLTMQM, Delete Message Queue Manager
  - ENDMQM, End Message Queue Manager
  - STRMQM, Start Message Queue Manager
- Security Commands
  - GRTMQMAUT, Grant IBM MQ Object Authority

  - RVKMQMAUT, Revoke IBM MQ Object Authority
- Trace Command
  - TRCMQM, Trace IBM MQ Job
- Transaction Commands
  - RSVMQMTRN, Resolve IBM MQ Transaction
- Trigger Monitor Commands
  - STRMQMTRM, Start Trigger Monitor
- IBM MQSC Commands
  - RUNMQSC, Run IBM MQSC Commands
  - STRMQMMQSC, Start IBM MQSC Commands

Group 2

The rest of the commands, for which two levels of authority are required:

1. IBM i authority to run the command. An IBM MQ administrator sets this using the **GRTOBJAUT** command to override the *PUBLIC(*EXCLUDE) restriction for a user or group of users.

   For example:

   ```
   GRTOBJAUT OBJ(QMQM/DSPMQMQ) OBJTYPE(*CMD) USER(MQUSER) AUT(*USE)
   ```
2. IBM MQ authority to manipulate the IBM MQ objects associated with the command, or commands, given the correct IBM i authority in Step 1.

   This authority is controlled by the user having the appropriate OAM authority for the required action, set by an IBM MQ administrator using the **GRTMQMAUT** command

   For example:

   ```
   GRTMQMAUT *connect authority to the queue manager + *admchg authority to
     the queue
   ```

The commands can be grouped as follows:

- Channel Commands
  - CHGMQMCHL, Change IBM MQ Channel

    This requires *connect authority to the queue manager and *admchg authority to the channel.
  - CPYMQMCHL, Copy IBM MQ Channel

    This requires *connect and *admcrt authority to the queue manager, *admdsp authority to the default channel type to be copied, and *admcrt authority to the channel object class.

    For example, copying a Sender channel, needs *admdsp authority to SYSTEM.DEF.SENDER channel
  - CRTMQMCHL, Create IBM MQ Channel

    This requires *connect and *admcrt authority to the queue manager, *admdsp authority to the default channel type to be created and *admcrt authority to the channel object class.

    For example, creating a Sender channel, needs *admdsp authority to SYSTEM.DEF.SENDER channel
  - DLTMQMCHL, Delete IBM MQ Channel

    This requires *connect authority to the queue manager and *admdlt authority to the channel.
  - RSVMQMCHL, Resolve IBM MQ Channel

    This requires *connect authority to the queue manager and *ctrlx authority to the channel.
- Display commands

  To process the DSP commands you must grant the user `*connect` and `*admdsp` authority to the queue manager, together with any specific option listed:
  - DSPMQM, Display Message Queue Manager

- DSPMQMAUT, Display IBM MQ Object Authority
- DSPMQMAUTI, Display IBM MQ Authentication Information - *admdsp to the authentication information object
- DSPMQMCHL, Display IBM MQ Channel - *admdsp to the channel
- DSPMQMCSVR, Display IBM MQ Command Server
- DSPMQMNL, Display IBM MQ Namelist - *admdsp to the namelist
- DSPMQMOBJN, Display IBM MQ Object Names
- DSPMQMPRC, Display IBM MQ Process - *admdsp to the process
- DSPMQMQ, Display IBM MQ Queue - *admdsp to the queue
- DSPMQMTOP, Display IBM MQ Topic - *admdsp to the topic

• Work with commands

  To process the WRK commands and display the options panel you must grant the user *connect and *admdsp authority to the queue manager, together with any specific option listed:
  - WRKMQM, Work with Message Queue Managers
  - WRKMQMAUT, Work with IBM MQ Object Authority
  - WRKMQMAUTD, Work with IBM MQ Object Authority Data
  - WRKMQMAUTI, Work with IBM MQ Authentication Information
    - *admchg for the Change IBM MQ Authentication Information Object command.
    - *admcrt for the Create and Copy IBM MQ Authentication Information Object command.
    - *admdlt for the Delete IBM MQ Authentication Information Object command.
    - *admdsp for the Display IBM MQ Authentication Information Object command.
  - WRKMQMCHL, Work with IBM MQ Channel

    This requires the following authorities:
    - *admchg for the Change IBM MQ Channel command.
    - *admclr for the Clear IBM MQ Channel command.
    - *admcrt for the Create and Copy IBM MQ Channel command.
    - *admdlt for the Delete IBM MQ Channel command.
    - *admdsp for the Display IBM MQ Channel command.
    - *ctrl for the Start IBM MQ Channel command.
    - *ctrl for the End IBM MQ Channel command.
    - *ctrl for the Ping IBM MQ Channel command.
    - *ctrlx for the Reset IBM MQ Channel command.
    - *ctrlx for the Resolve IBM MQ Channel command.
  - WRKMQMCHST, Work with IBM MQ Channel Status

    This requires *admdsp authority to the channel.
  - WRKMQMCL, Work with IBM MQ Clusters
  - WRKMQMCLQ, Work with IBM MQ Cluster Queues
  - WRKMQMCLQM, Work with IBM MQ Cluster Queue Manager
  - WRKMQMLSR, Work with IBM MQ Listener
  - WRKMQMMSG, Work with IBM MQ Messages

    This requires *browse authority to the queue
  - WRKMQMNL, Work with IBM MQ Namelists

    This requires the following authorities:
    - *admchg for the Change IBM MQ Namelist command.
    - *admcrt for the Create and Copy IBM MQ Namelist command.

    - `*admdlt` for the Delete IBM MQ Namelist command.
    - `*admdsp` for the Display IBM MQ Namelist command.
  - WRKMQMPRC, Work with IBM MQ Processes

    This requires the following authorities:
    - `*admchg` for the Change IBM MQ Process command.
    - `*admcrt` for the Create and Copy IBM MQ Process command.
    - `*admdlt` for the Delete IBM MQ Process command.
    - `*admdsp` for the Display IBM MQ Process command.
  - WRKMQMQ, Work with IBM MQ queues

    This requires the following authorities:
    - `*admchg` for the Change IBM MQ Queue command.
    - `*admclr` for the Clear IBM MQ Queue command.
    - `*admcrt` for the Create and Copy IBM MQ Queue command.
    - `*admdlt` for the Delete IBM MQ Queue command.
    - `*admdsp` for the Display IBM MQ Queue command.
  - WRKMQMQSTS, Work with IBM MQ Queue Status
  - WRKMQMTOP, Work with IBM MQ Topics

    This requires the following authorities
    - `*admchg` for the Change IBM MQ Topic command.
    - `*admcrt` for the Create and Copy IBM MQ Topic command.
    - `*admdlt` for the Delete IBM MQ Topic command.
    - `*admdsp` for the Display IBM MQ Topic command.
  - WRKMQMSUB, Work with IBM MQ Subscriptions
- Other Channel commands

  To process the channel commands you must grant the user the specific authorities listed:
  - ENDMQMCHL, End IBM MQ Channel

    This requires `*connect` authority to the queue manager and `*allmqi` authority to the transmission queue associated with the channel.
  - ENDMQMLSR, End IBM MQ Listener

    This requires `*connect` authority to the queue manager and `*ctrl` authority to the named listener object.
  - PNGMQMCHL, Ping IBM MQ Channel

    This requires `*connect` and `*inq` authority to the queue manager and `*ctrl` authority to the channel object.
  - RSTMQMCHL, Reset IBM MQ Channel

    This requires `*connect` authority to the queue manager.
  - STRMQMCHL, Start IBM MQ Channel

    This requires `*connect` authority to the queue manager and `*ctrl` authority to the channel object.
  - STRMQMCHLI, Start IBM MQ Channel Initiator

    This requires `*connect` and `*inq` authority to the queue manager, and `*allmqi` authority to the initiation queue associated with the transmission queue of the channel.
  - STRMQMLSR, Start IBM MQ Listener

    This requires *connect authority to the queue manager and *ctrl authority to the named listener object.
- Other commands:

To process the following commands you must grant the user the specific authorities listed:

- CCTMQM, Connect to Message Queue Manager

  This requires no IBM MQ object authority.
- CHGMQM, Change Message Queue Manager

  This requires `*connect` and `*admchg` authority to the queue manager.
- CHGMQMAUTI, Change IBM MQ Authentication Information

  This requires `*connect` authority to the queue manager and `*admchg` and `*admdsp` authority to the authentication information object.
- CHGMQMNL, Change IBM MQ Namelist

  This requires `*connect` authority to the queue manager and `*admchg` authority to the namelist.
- CHGMQMPRC, Change IBM MQ Process

  This requires `*connect` authority to the queue manager and `*admchg` authority to the process.
- CHGMQMQ, Change IBM MQ Queue

  This requires `*connect` authority to the queue manager and `*admchg` authority to the queue.
- CLRMQMQ, Clear IBM MQ Queue

  This requires `*connect` authority to the queue manager and `*admclr` authority to the queue.
- CPYMQMAUTI, Copy IBM MQ Authentication Information

  This requires `*connect` authority to the queue manager and `*admdsp` authority to the authentication information object and `*admcrt` authority to the authentication information object class.
- CPYMQMNL, Copy IBM MQ Namelist

  This requires `*connect` and `*admcrt` authority to the queue manager.
- CPYMQMPRC, Copy IBM MQ Process

  This requires `*connect` and `*admcrt` authority to the queue manager.
- CPYMQMQ, Copy IBM MQ Queue

  This requires `*connect` and `*admcrt` authority to the queue manager.
- CRTMQMAUTI, Create IBM MQ Authentication Information

  This requires `*connect` authority to the queue manager and `*admdsp` authority to the authentication information object and `*admcrt` authority to the authentication information object class.
- CRTMQMNL, Create IBM MQ Namelist

  This requires `*connect` and `*admcrt` authority to the queue manager and `*admdsp` authority to the default namelist.
- CRTMQMPRC, Create IBM MQ Process

  This requires `*connect` and `*admcrt` authority to the queue manager and `*admdsp` authority to the default process.
- CRTMQMQ, Create IBM MQ Queue

  This requires `*connect` and `*admcrt` authority to the queue manager and `*admdsp` authority to the default queue.
- CVTMQMDTA, Convert IBM MQ Data Type Command

  This requires no IBM MQ object authority.
- DLTMQMAUTI, Delete IBM MQ Authentication Information

  This requires `*connect` authority to the queue manager and `*ctrlx` authority to the authentication information object.
- DLTMQMNL, Delete IBM MQ Namelist

This requires `*connect` authority to the queue manager and `*admdlt` authority to the namelist.
- DLTMQMPRC, Delete IBM MQ Process

  This requires `*connect` authority to the queue manager and `*admdlt` authority to the process.
- DLTMQMQ, Delete IBM MQ Queue

  This requires `*connect` authority to the queue manager and `*admdlt` authority to the queue.
- DSCMQM, Disconnect from Message Queue Manager

  This requires no IBM MQ object authority.
- RFRMQMAUT, Refresh Security

  This requires `*connect` authority to the queue manager.
- RFRMQMCL, Refresh Cluster

  This requires `*connect` authority to the queue manager.
- RSMMQMCLQM, Resume Cluster Queue Manager

  This requires `*connect` authority to the queue manager.
- RSTMQMCL, Reset Cluster

  This requires `*connect` authority to the queue manager.
- SPDMQMCLQM, Suspend Cluster Queue Manager

  This requires `*connect` authority to the queue manager.

Access authorizations on IBM i

Use this information to understand the access authorization commands.

Authorizations defined by the AUT keyword on the **GRTMQMAUT** and **RVKMQMAUT** commands can be categorized as follows:
- Authorizations related to MQI calls
- Authorization-related administration commands
- Context authorizations
- General authorizations, that is, for MQI calls, for commands, or both

The following tables list the different authorities, using the AUT parameter for MQI calls, Context calls, MQSC and PCF commands, and generic operations.

Table 27. Authorizations for MQI calls

AUT	Description
***ALTUSR**	Allow another user's authority to be used for MQOPEN and MQPUT1 calls.
***BROWSE**	Retrieve a message from a queue by issuing an MQGET call with the BROWSE option.
***CONNECT**	Connect the application to the specified queue manager by issuing an MQCONN call.
***GET**	Retrieve a message from a queue by issuing an MQGET call.
***INQ**	Make an inquiry on a specific queue by issuing an MQINQ call.
***PUB**	Open a topic to publish a message using an MQPUT call.
***PUT**	Put a message on a specific queue by issuing an MQPUT call.
***RESUME**	Resume a subscription using an MQSUB call.
***SET**	Set attributes on a queue from the MQI by issuing an MQSET call. If you open a queue for multiple options, you must be authorized for each of them.
***SUB**	Create, Alter or Resume a subscription to a topic using an MQSUB call.

Table 28. Authorizations for context calls

AUT	Description
***PASSALL**	Pass all context on the specified queue. All the context fields are copied from the original request.
***PASSID**	Pass identity context on the specified queue. The identity context is the same as that of the request.
***SETALL**	Set all context on the specified queue. This is used by special system utilities.
***SETID**	Set identity context on the specified queue. This is used by special system utilities.

Table 29. Authorizations for MQSC and PCF calls

AUT	Description
***ADMCHG**	Change the attributes of the specified object.
***ADMCLR**	Clear the specified object (PCF Clear object command only).
***ADMCRT**	Create objects of the specified type.
***ADMDLT**	Delete the specified object.
***ADMDSP**	Display the attributes of the specified object.

Table 30. Authorizations for generic operations

AUT	Description
***ALL**	Use all operations applicable to the object. `all` authority is equivalent to the union of the authorities `alladm`, `allmqi`, and `system` appropriate to the object type.
***ALLADM**	Perform all administration operations applicable to the object.
***ALLMQI**	Use all MQI calls applicable to the object.
***CTRL**	Control startup and shutdown of channels, listeners, and services.
***CTRLX**	Reset sequence number and resolve indoubt channels.

Using the access authorization commands on IBM i

Use this information to learn about the access authorization commands, and use the command examples.

Using the GRTMQMAUT command

If you have the required authorization, you can use the **GRTMQMAUT** command to grant authorization of a user profile or user group to access a particular object. The following examples illustrate how the **GRTMQMAUT** command is used:

1.
   ```
   GRTMQMAUT OBJ(RED.LOCAL.QUEUE) OBJTYPE(*LCLQ) USER(GROUPA) +
             AUT(*BROWSE *PUT) MQMNAME('saturn.queue.manager')
   ```

   In this example:

   - `RED.LOCAL.QUEUE` is the object name.
   - `*LCLQ` (local queue) is the object type.
   - `GROUPA` is the name of a user profile on the system for which authorizations are to change. This profile can be used as a group profile for other users.
   - `*BROWSE` and `*PUT` are the authorizations being granted to the specified queue.

     `*BROWSE` adds authorization to browse messages on the queue (to issue MQGET with the browse option).

     `*PUT` adds authorization to put (MQPUT) messages on the queue.
   - `saturn.queue.manager` is the queue manager name.

2. The following command grants to users JACK and JILL all applicable authorizations, to all process definitions, for the default queue manager.

   ```
   GRTMQMAUT OBJ(*ALL) OBJTYPE(*PRC) USER(JACK JILL) AUT(*ALL)
   ```
3. The following command grants user GEORGE authority to put a message on the queue ORDERS, on the queue manager TRENT.

   ```
   GRTMQMAUT OBJ(TRENT) OBJTYPE(*MQM) USER(GEORGE) AUT(*CONNECT) MQMNAME (TRENT)
   GRTMQMAUT OBJ(ORDERS) OBJTYPE(*Q) USER(GEORGE) AUT(*PUT) MQMNAME (TRENT)
   ```

Using the RVKMQMAUT command

If you have the required authorization, you can use the **RVKMQMAUT** command to remove previously granted authorization of a user profile or user group to access a particular object. The following examples illustrate how the **RVKMQMAUT** command is used:

1.
   ```
   RVKMQMAUT OBJ(RED.LOCAL.QUEUE) OBJTYPE(*LCLQ) USER(GROUPA) +
   AUT(*PUT) MQMNAME('saturn.queue.manager')
   ```

   The authority to put messages to the specified queue, that was granted in the previous example, is removed for GROUPA.

2.
   ```
   RVKMQMAUT OBJ(PAY*) OBJTYPE(*Q) USER(*PUBLIC) AUT(*GET) +
   MQMNAME(PAYROLLQM)
   ```

   Authority to get messages from any queue with a name starting with the characters PAY, owned by queue manager PAYROLLQM, is removed from all users of the system unless they, or a group to which they belong, have been separately authorized.

Using the DSPMQMAUT command

The display MQM authority (**DSPMQMAUT**) command shows, for the specified object and user, the list of authorizations that the user has for the object. The following example illustrates how the command is used:

```
DSPMQMAUT OBJ(ADMINNL) OBJTYPE(*NMLIST) USER(JOE) OUTPUT(*PRINT) +
MQMNAME(ADMINQM)
```

Using the RFRMQMAUT command

The refresh MQM security (**RFRMQMAUT**) command enables you to update the OAM's authorization group information immediately, reflecting changes made at the operating system level, without needing to stop and restart the queue manager. The following example illustrates how the command is used:

```
RFRMQMAUT MQMNAME(ADMINQM)
```

Authorization specification tables for IBM i

Use this information to determine what authorization is required to use particular API calls, and particular options of those calls, on queue objects, process objects, and queue manager objects.

The authorization specification tables starting in Table 31 on page 549 define precisely how the authorizations work and the restrictions that apply. The tables apply to these situations:
- Applications that issue MQI calls
- Administration programs that issue MQSC commands as escape PCFs
- Administration programs that issue PCF commands

In this section, the information is presented as a set of tables that specify the following data:

Action to be performed
MQI option, MQSC command, or PCF command.

Access control object
Queue, process definition, queue manager, namelist, channel, client connection channel, listener, service, or authentication information object.

Authorization required
Expressed as an MQZAO_ constant.

In the tables, the constants prefixed by MQZAO_ correspond to the keywords in the authorization list for the **GRTMQMAUT** and **RVKMQMAUT** commands for the particular entity. For example, MQZAO_BROWSE corresponds to the keyword *BROWSE ; similarly, the keyword MQZAO_SET_ALL_CONTEXT corresponds to the keyword *SETALL, and so on. These constants are defined in the header file cmqzc.h, which is supplied with the product.

MQI authorizations

An application is allowed to issue specific MQI calls and options only if the user identifier under which it is running (or whose authorizations it is able to assume) has been granted the relevant authorization.

Four MQI calls require authorization checks: MQCONN, MQOPEN, MQPUT1, and MQCLOSE.

For MQOPEN and MQPUT1, the authority check is made on the name of the object being opened, and not on the name, or names, resulting after a name has been resolved. For example, an application can be granted authority to open an alias queue without having authority to open the base queue to which the alias resolves. The rule is that the check is carried out on the first definition encountered during the process of name resolution that is not a queue-manager alias, unless the queue-manager alias definition is opened directly; that is, its name appears in the *ObjectName* field of the object descriptor. Authority is always needed for the particular object being opened; in some cases additional queue-independent authority, obtained through an authorization for the queue-manager object, is required.

Table 31 on page 549, Table 32 on page 549, Table 33 on page 549, and Table 34 on page 550 summarize the authorizations needed for each call.

Note: These tables do not mention namelists, channels, client connection channels, listeners, services, or authentication information objects. This is because none of the authorizations apply to these objects, except for MQOO_INQUIRE, for which the same authorizations apply as for the other objects.

Table 31. Security authorization needed for MQCONN calls

Authorization required for:	Queue object (**1 on page 550**)	Process object	Queue manager object
MQCONN option	Not applicable	Not applicable	MQZAO_CONNECT

Table 32. Security authorization needed for MQOPEN calls

Authorization required for:	Queue object (**1 on page 550**)	Process object	Queue manager object
MQOO_INQUIRE	MQZAO_INQUIRE **(2 on page 550)**	MQZAO_INQUIRE **(2 on page 550)**	MQZAO_INQUIRE **(2 on page 550)**
MQOO_BROWSE	MQZAO_BROWSE	Not applicable	No check
MQOO_INPUT_*	MQZAO_INPUT	Not applicable	No check
MQOO_SAVE_ ALL_CONTEXT **(3 on page 550)**	MQZAO_INPUT	Not applicable	Not applicable
MQOO_OUTPUT (Normal queue) **(4 on page 550)**	MQZAO_OUTPUT	Not applicable	Not applicable
MQOO_PASS_ IDENTITY_CONTEXT **(5 on page 550)**	MQZAO_PASS_ IDENTITY_CONTEXT	Not applicable	No check
MQOO_PASS_ALL_ CONTEXT **(5 on page 550, 6 on page 550)**	MQZAO_PASS _ALL_CONTEXT	Not applicable	No check
MQOO_SET_ IDENTITY_CONTEXT **(5 on page 550, 6 on page 550)**	MQZAO_SET_ IDENTITY_CONTEXT	Not applicable	MQZAO_SET_ IDENTITY_CONTEXT **(7 on page 550)**
MQOO_SET_ ALL_CONTEXT **(5 on page 550, 8 on page 550)**	MQZAO_SET_ ALL_CONTEXT	Not applicable	MQZAO_SET_ ALL_CONTEXT **(7 on page 550)**
MQOO_OUTPUT (Transmission queue) **(9 on page 550)**	MQZAO_SET_ ALL_CONTEXT	Not applicable	MQZAO_SET_ ALL_CONTEXT **(7 on page 550)**
MQOO_SET	MQZAO_SET	Not applicable	No check
MQOO_ALTERNATE_ USER_AUTHORITY	**(10 on page 550)**	**(10 on page 550)**	MQZAO_ALTERNATE_ USER_AUTHORITY **(10 on page 550, 11 on page 550)**

Table 33. Security authorization needed for MQPUT1 calls

Authorization required for:	Queue object (**1 on page 550**)	Process object	Queue manager object
MQPMO_PASS_ IDENTITY_CONTEXT	MQZAO_PASS_ IDENTITY_CONTEXT **(12 on page 550)**	Not applicable	No check
MQPMO_PASS_ALL _CONTEXT	MQZAO_PASS_ ALL_CONTEXT **(12 on page 550)**	Not applicable	No check
MQPMO_SET_ IDENTITY_CONTEXT	MQZAO_SET_ IDENTITY_CONTEXT **(12 on page 550)**	Not applicable	MQZAO_SET_ IDENTITY_CONTEXT **(7 on page 550)**

Table 33. Security authorization needed for MQPUT1 calls (continued)

Authorization required for:	**Queue object (1)**	**Process object**	**Queue manager object**
MQPMO_SET_ ALL_CONTEXT	MQZAO_SET_ ALL_CONTEXT **(12)**	Not applicable	MQZAO_SET_ ALL_CONTEXT **(7)**
(Transmission queue) **(9)**	MQZAO_SET_ ALL_CONTEXT	Not applicable	MQZAO_SET_ ALL_CONTEXT **(7)**
MQPMO_ALTERNATE_ USER_AUTHORITY	**(13)**	Not applicable	MQZAO_ALTERNATE_ USER_AUTHORITY **(11)**

Table 34. Security authorization needed for MQCLOSE calls

Authorization required for:	**Queue object (1)**	**Process object**	**Queue manager object**
MQCO_DELETE	MQZAO_DELETE **(14)**	Not applicable	Not applicable
MQCO_DELETE _PURGE	MQZAO_DELETE **(14)**	Not applicable	Not applicable

Notes for the tables:

1. If a model queue is being opened:
   - MQZAO_DISPLAY authority is needed for the model queue, in addition to the authority to open the model queue for the type of access for which you are opening.
   - MQZAO_CREATE authority is not needed to create the dynamic queue.
   - The user identifier used to open the model queue is automatically granted all the queue-specific authorities (equivalent to MQZAO_ALL) for the dynamic queue created.
2. Either the queue, process, namelist, or queue manager object is checked, depending on the type of object being opened.
3. MQOO_INPUT_* must also be specified. This option is valid for a local, model, or alias queue.
4. This check is performed for all output cases, except the case specified in note 9.
5. MQOO_OUTPUT must also be specified.
6. MQOO_PASS_IDENTITY_CONTEXT is also implied by this option.
7. This authority is required for both the queue manager object and the particular queue.
8. MQOO_PASS_IDENTITY_CONTEXT, MQOO_PASS_ALL_CONTEXT, and MQOO_SET_IDENTITY_CONTEXT are also implied by this option.
9. This check is performed for a local or model queue that has a *Usage* queue attribute of MQUS_TRANSMISSION, and is being opened directly for output. It does not apply if a remote queue is being opened (either by specifying the names of the remote queue manager and remote queue, or by specifying the name of a local definition of the remote queue).
10. At least one of MQOO_INQUIRE (for any object type), or (for queues) MQOO_BROWSE, MQOO_INPUT_*, MQOO_OUTPUT, or MQOO_SET must also be specified. The check carried out is as for the other options specified, using the supplied alternate-user identifier for the specific-named object authority, and the current application authority for the MQZAO_ALTERNATE_USER_IDENTIFIER check.
11. This authorization allows any *AlternateUserId* to be specified.
12. An MQZAO_OUTPUT check is also carried out if the queue does not have a *Usage* queue attribute of MQUS_TRANSMISSION.
13. The check carried out is as for the other options specified, using the supplied alternate-user identifier for the named queue authority, and the current application authority for the MQZAO_ALTERNATE_USER_IDENTIFIER check.
14. The check is carried out only if both of the following are true:

- A permanent dynamic queue is being closed and deleted.
- The queue was not created by the MQOPEN that returned the object handle being used.

Otherwise, there is no check.

General notes:

1. The special authorization MQZAO_ALL_MQI includes all the following authorizations that are relevant to the object type:
   - MQZAO_CONNECT
   - MQZAO_INQUIRE
   - MQZAO_SET
   - MQZAO_BROWSE
   - MQZAO_INPUT
   - MQZAO_OUTPUT
   - MQZAO_PASS_IDENTITY_CONTEXT
   - MQZAO_PASS_ALL_CONTEXT
   - MQZAO_SET_IDENTITY_CONTEXT
   - MQZAO_SET_ALL_CONTEXT
   - MQZAO_ALTERNATE_USER_AUTHORITY
2. MQZAO_DELETE (see note 14 on page 550) and MQZAO_DISPLAY are classed as administration authorizations. They are not therefore included in MQZAO_ALL_MQI.
3. *No check* means that no authorization checking is carried out.
4. *Not applicable* means that authorization checking is not relevant to this operation. For example, you cannot issue an MQPUT call to a process object.

Authorizations for MQSC commands in escape PCFs on IBM i

These authorizations allow a user to issue administration commands as an escape PCF message. These methods allow a program to send an administration command as a message to a queue manager, for execution on behalf of that user.

This section summarizes the authorizations needed for each MQSC command contained in Escape PCF.

Not applicable means that authorization checking is not relevant to this operation.

The user ID under which the program that submits the command is running must also have the following authorities:

- MQZAO_CONNECT authority to the queue manager
- DISPLAY authority on the queue manager in order to perform PCF commands
- Authority to issue the MQSC commands within the text of the Escape PCF command

Service	MQZAO_CONTROL

Note:
1. For DEFINE commands, MQZAO_DISPLAY authority is also needed for the LIKE object if one is specified, or on the appropriate SYSTEM.DEFAULT.xxx object if LIKE is omitted.
2. The MQZAO_CREATE authority is not specific to a particular object or object type. Create authority is granted for all objects for a specified queue manager, by specifying an object type of QMGR on the **GRTMQMAUT** command.
3. This option applies if the object to be replaced already exists. If it does not, the check is as for DEFINE *object* NOREPLACE.

Authorizations for PCF commands on IBM i

These authorizations allow a user to issue administration commands as PCF commands. These methods allow a program to send an administration command as a message to a queue manager, for execution on behalf of that user.

This section summarizes the authorizations needed for each PCF command.

No check means that no authorization checking is carried out; *Not applicable* means that authorization checking is not relevant to this operation.

The user ID under which the program that submits the command is running must also have the following authorities:

- MQZAO_CONNECT authority to the queue manager
- DISPLAY authority on the queue manager in order to perform PCF commands

The special authorization MQZAO_ALL_ADMIN includes the following authorizations:

- MQZAO_CHANGE
- MQZAO_CLEAR
- MQZAO_DELETE
- MQZAO_DISPLAY
- MQZAO_CONTROL
- MQZAO_CONTROL_EXTENDED

MQZAO_CREATE is not included as it is not specific to a particular object or object type

Note:

1. For Copy commands, MQZAO_DISPLAY authority is also needed for the From object.
2. The MQZAO_CREATE authority is not specific to a particular object or object type. Create authority is granted for all objects for a specified queue manager, by specifying an object type of QMGR on the **GRTMQMAUT** command.
3. For Create commands, MQZAO_DISPLAY authority is also needed for the appropriate SYSTEM.DEFAULT.* object.
4. This option applies if the object to be replaced already exists. If it does not, the check is as for Copy or Create without replace.

Generic OAM profiles on IBM i

Object authority manager (OAM) generic profiles enable you to set the authority a user has to many objects at once, rather than having to issue separate **GRTMQMAUT** commands against each individual object when it is created. Using generic profiles in the **GRTMQMAUT** command enables you to set a generic authority for all future objects created that fit that profile.

The rest of this section describes the use of generic profiles in more detail:
- "Using wildcard characters"
- "Profile priorities"

Using wildcard characters

What makes a profile generic is the use of special characters (wildcard characters) in the profile name. For example, the question mark (?) wildcard character matches any single character in a name. So, if you specify ABC.?EF, the authorization you give to that profile applies to any objects created with the names ABC.DEF, ABC.CEF, ABC.BEF, and so on.

The wildcard characters available are:

? Use the question mark (?) instead of any single character. For example, AB.?D would apply to the objects AB.CD, AB.ED, and AB.FD.

* Use the asterisk (*) as:
- A *qualifier* in a profile name to match any one qualifier in an object name. A qualifier is the part of an object name delimited by a period. For example, in ABC.DEF.GHI, the qualifiers are ABC, DEF, and GHI.

  For example, ABC.*.JKL would apply to the objects ABC.DEF.JKL, and ABC.GHI.JKL. (Note that it would **not** apply to ABC.JKL ; * used in this context always indicates one qualifier.)
- A character within a qualifier in a profile name to match zero or more characters within the qualifier in an object name.

  For example, ABC.DE*.JKL would apply to the objects ABC.DE.JKL, ABC.DEF.JKL, and ABC.DEGH.JKL.

** Use the double asterisk (**) ***once*** in a profile name as:
- The entire profile name to match all object names. For example, if you use the keyword OBJTYPE (*PRC) to identify processes, then use ** as the profile name, you change the authorizations for all processes.
- As either the beginning, middle, or ending qualifier in a profile name to match zero or more qualifiers in an object name. For example, **.ABC identifies all objects with the final qualifier ABC.

Profile priorities

An important point to understand when using generic profiles is the priority that profiles are given when deciding what authorities to apply to an object being created. For example, suppose that you have issued the commands:

```
GRTMQMAUT OBJ(AB.*) OBJTYPE(*Q) USER(FRED) AUT(*PUT) MQMNAME(MYQMGR)
GRTMQMAUT OBJ(AB.C*) OBJTYPE(*Q) USER(FRED) AUT(*GET) MQMNAME(MYQMGR)
```

The first gives put authority to all queues for the principal FRED with names that match the profile AB.*; the second gives get authority to the same types of queue that match the profile AB.C*.

Suppose that you now create a queue called AB.CD. According to the rules for wildcard matching, either GRTMQMAUT could apply to that queue. So, does it have put or get authority?

To find the answer, you apply the rule that, whenever multiple profiles can apply to an object, **only the most specific applies**. The way that you apply this rule is by comparing the profile names from left to right. Wherever they differ, a non-generic character is more specific than a generic character. So, in the previous example, the queue AB.CD has **get** authority (AB.C* is more specific than AB.*).

When you are comparing generic characters, the order of *specificity* is:
1. ?
2. *
3. **

Specifying the installed authorization service on IBM i

You can specify which authorization service component to use.

The parameter **`Service Component name`** on **`GRTMQMAUT`** and **`RVKMQMAUT`** allows you to specify the name of the installed authorization service component.

Selecting **F24** on the initial panel, followed by **F9=All parameters** on the next panel of either command, allows you to specify either the installed authorization component (*DFT) or the name of the required authorization service component specified in the Service stanza of the queue manager's qm.ini file.

`DSPMQMAUT` also has this extra parameter. This parameter allows you to search all the installed authorization components (*DFT), or the specified authorization-service component name, for the specified object name, object type, and user

Working with and without authority profiles on IBM i

Use this information to learn how to work with authority profiles and how to work without authority profiles.

You can work with authority profiles, as explained in "Working with authority profiles," or without them, as explained here:

To work without authority profiles, use `*NONE` as an Authority parameter on **`GRTMQMAUT`** to create profiles without authority. This leaves any existing profiles unchanged.

On **`RVKMQMAUT`**, use `*REMOVE` as an Authority parameter to remove an existing authority profile.

Working with authority profiles

There are two commands associated with authority profiling:
- **`WRKMQMAUT`**
- **`WRKMQMAUTD`**

You can access these commands directly from the command line, or from the WRKMQM panel by:
1. Typing in the queue manager name and pressing the `Enter` key to access the **`WRKMQM`** results panel.
2. Selecting `F23=More options` on this panel.

Option 24 selects the results panel for the **`WRKMQMAUT`** command and option 25 selects the **`WRKMQMAUTI`** command, which is used with the SSL bindings layer.

WRKMQMAUT

This command allows you to work with the authority data held in the authority queue.

Note: To run this command you must have `*connect` and `*admdsp` authority to the queue manager. However, to create or delete a profile, you need QMQMADM authority.

If you output the information to the screen, a list of authority profile names, together with their types, is displayed. If you print the output, you receive a detailed list of all the authority data, the registered users, and their authorities.

Entering an object or profile name on this panel, and pressing ENTER takes you to the results panel for **`WRKMQMAUT`** .

If you select `4=Delete`, you go to a new panel from which you can confirm that you want to delete all the user names registered to the generic authority profile name you specify. This option runs **`RVKMQMAUT`** with the option *REMOVE for all the users, and applies **only** to generic profile names.

If you select `12=Work with profile` you go to the **`WRKMQMAUTD`** command results panel, as explained in "WRKMQMAUTD."

WRKMQMAUTD

This command allows you to display all the users registered with a particular authority profile name and object type. To run this command you must have `*connect` and `*admdsp` authority to the queue manager. However, to grant, run, create, or delete a profile you need QMQMADM authority.

Selecting `F24=More keys` from the initial input panel, followed by option `F9=All Parameters` displays the Service Component Name as for **`GRTMQMAUT`** and **`RVKMQMAUT`**.

Note: The `F11=Display Object Authorizations` key toggles between the following types of authorities:
- Object authorizations
- Context authorizations
- MQI authorizations

The options on the screen are:

2=Grant
Takes you to the **`GRTMQMAUT`** panel to add to the current authorities.

3=Revoke
Takes you to the **`RVKMQMAUT`** panel to remove some of the current definitions

4=Delete
Takes you to a panel that allows you to delete the authority data for specified users. This runs **`RVKMQMAUT`** with the option *REMOVE.

5=Display
Takes you to the existing **`DSPMQMAUT`** command

F6=Create
Takes you to the **`GRTMQMAUT`** panel that allows you to create a profile authority record.

Object authority manager guidelines for IBM i

Additional hints and tips for using the object authority manager (OAM)

Limit access to sensitive operations

Some operations are sensitive; limit them to privileged users. For example,

- Accessing some special queues, such as transmission queues or the command queue `SYSTEM.ADMIN.COMMAND.QUEUE`
- Running programs that use full MQI context options
- Creating and copying application queues

Queue manager directories

The directories and libraries containing queues and other queue manager data are private to the product. Do not use standard operating system commands to grant or revoke authorizations to MQI resources.

Queues

The authority to a dynamic queue is based on, but is not necessarily the same as, that of the model queue from which it is derived.

For alias queues and remote queues, the authorization is that of the object itself, not the queue to which the alias or remote queue resolves. It is possible to authorize a user profile to access an alias queue that resolves to a local queue to which the user profile has no access permissions.

Limit the authority to create queues to privileged users. If you do not, users can bypass the normal access control by creating an alias.

Alternate-user authority

Alternate-user authority controls whether one user profile can use the authority of another user profile when accessing an IBM MQ object. This technique is essential where a server receives requests from a program and the server wants to ensure that the program has the required authority for the request. The server might have the required authority, but it needs to know whether the program has the authority for the actions it has requested.

For example:

- A server program running under user profile PAYSERV retrieves a request message from a queue that was put on the queue by user profile USER1.
- When the server program gets the request message, it processes the request and puts the reply back into the reply-to queue specified with the request message.
- Instead of using its own user profile (PAYSERV) to authorize opening the reply-to queue, the server can specify some other user profile, in this case, USER1. In this example, you can use alternate-user authority to control whether PAYSERV is allowed to specify USER1 as an alternate-user profile when it opens the reply-to queue.

The alternate-user profile is specified on the *`AlternateUserId`* field of the object descriptor.

Note: You can use alternate-user profiles on any IBM MQ object. Use of an alternate-user profile does not affect the user profile used by any other resource managers.

Context authority

Context is information that applies to a particular message and is contained in the message descriptor, MQMD, which is part of the message.

For descriptions of the message descriptor fields relating to context, see MQMD overview.

For information about the context options, see Message context.

Remote security considerations

For remote security, consider:

Put authority
: For security across queue managers, you can specify the put authority that is used when a channel receives a message sent from another queue manager.

  This parameter is valid only for RCVR, RQSTR, or CLUSRCVR channel types. Specify the channel attribute PUTAUT as follows:

  DEF Default user profile. This is the QMQM user profile under which the message channel agent is running.

  CTX The user profile in the message context.

Transmission queues
: Queue managers automatically put remote messages on a transmission queue; no special authority is required. However, putting a message directly on a transmission queue requires special authorization.

Channel exits
: Channel exits can be used for added security.

Channel authentication records
: Use to exercise more precise control over the access granted to connecting systems at a channel level.

For more information about remote security, see "Channel authorization" on page 485.

Protecting channels with SSL or TLS

The Secure Sockets Layer (SSL) and Transport Layer Security (TLS) protocols provide channel security, with protection against eavesdropping, tampering, and impersonation. IBM MQ support for SSL and TLS enables you to specify, on the channel definition, that a particular channel uses SSL or TLS security. You can also specify details of the security you want, such as the encryption algorithm you want to use.

SSL and TLS support in IBM MQ uses the queue manager *authentication information object* and various CL and MQSC commands and queue manager and channel parameters that define the SSL or TLS support required in detail.

The following CL commands support SSL or TLS:

WRKMQMAUTI
: Work with the attributes of an authentication information object.

CHGMQMAUTI
: Modify the attributes of an authentication information object.

CRTMQMAUTI
: Create an authentication information object.

CPYMQMAUTI
Create an authentication information object by copying an existing one.

DLTMQMAUTI
Delete an authentication information object.

DSPMQMAUTI
Displays the attributes for a specific authentication information object.

For an overview of channel security using SSL or TLS, see
- Protecting channels with SSL

For details of PCF commands associated with SSL, see
- Change, Copy, and Create Authentication Information Object
- Delete Authentication Information Object
- Inquire Authentication Information Object

Setting up security on z/OS

Security considerations specific to z/OS.

Security in IBM MQ for z/OS is controlled using RACF or an equivalent external security manager (ESM).

If a userid has `uid0`, it has access to the entire file system, that is, Superuser access. Under RACF, the only way to restrict this is by using the feature FSACCESS, which can restrict access at the file system level by RACF userid. For more information, see Using the FSACCESS class profile to restrict access in the *z/OS UNIX System Services Planning* documentation.

The following instructions assume that you are using RACF.

Related information:
Security scenario: two queue managers on z/OS
Security scenario: queue-sharing group on z/OS

RACF security classes

RACF classes are used to hold the profiles required for IBM MQ security checking. Many of the member classes have equivalent group classes. You must activate the classes and enable them to accept generic profiles

Each RACF class holds one or more profiles used at some point in the checking sequence, as shown in Table 35.

Table 35. RACF classes used by IBM MQ

Member class	Group class	Contents
MQADMIN	GMQADMIN	Profiles: Used mainly for holding profiles for administration-type functions. For example: • Profiles for IBM MQ security switches • The RESLEVEL security profile • Profiles for alternate user security • The context security profile • Profiles for command resource security

Table 35. RACF classes used by IBM MQ (continued)

Member class	Group class	Contents
MXADMIN	GMXADMIN	Profiles: Used mainly for holding profiles for administration-type functions. For example: • Profiles for IBM MQ security switches • The RESLEVEL security profile • Profiles for alternate user security • The context security profile • Profiles for command resource security This class can hold both uppercase and mixed case RACF profiles.
MQCONN		Profiles used for connection security
MQCMDS		Profiles used for command security
MQQUEUE	GMQQUEUE	Profiles used in queue resource security
MXQUEUE	GMXQUEUE	Mixed case and uppercase profiles used in queue resource security
MQPROC	GMQPROC	Profiles used in process resource security
MXPROC	GMXPROC	Mixed case and uppercase profiles used in process resource security
MQNLIST	GMQNLIST	Profiles used in namelist resource security
MXNLIST	GMXNLIST	Mixed case and uppercase profiles used in namelist resource security
MXTOPIC	GMXTOPIC	Mixed case and uppercase profiles used in topic security

Some classes have a related *group class* that enables you to put together groups of resources that have similar access requirements. For details about the difference between the member and group classes and when to use a member or group class, see the *z/OS SecureWay Security Server RACF Security Administrator's Guide*.

The classes must be activated before security checks can be made. To activate all the IBM MQ classes, you can use this RACF command:

```
SETROPTS CLASSACT(MQADMIN,MXADMIN,MQQUEUE,MXQUEUE,MQPROC,MXPROC,
                 MQNLIST,MXNLIST,MXTOPIC,MQCONN,MQCMDS)
```

You should also ensure that you set up the classes so that they can accept generic profiles. You also do this with the RACF command SETROPTS, for example:

```
SETROPTS GENERIC(MQADMIN,MXADMIN,MQQUEUE,MXQUEUE,MQPROC,MXPROC,
                MQNLIST,MXNLIST,MXTOPIC,MQCONN,MQCMDS)
```

RACF profiles

All RACF profiles used by IBM MQ contain a prefix, which is either the queue manager name or the queue-sharing group name. Be careful when you use the percent sign as a wildcard.

All RACF profiles used by IBM MQ contain a prefix. For queue-sharing group level security, this is the queue-sharing group name. For queue manager level security, the prefix is the queue manager name. If you are using a mixture of queue manager and queue-sharing group level security, you will use profiles with both types of prefix. (Queue-sharing group and queue manager level security are described in IBM MQ for z/OS concepts: security.)

For example, if you want to protect a queue called QUEUE_FOR_SUBSCRIBER_LIST in queue-sharing group QSG1 at queue-sharing group level, the appropriate profile would be defined to RACF as:

```
RDEFINE MQQUEUE QSG1.QUEUE_FOR_SUBSCRIBER_LIST
```

If you want to protect a queue called QUEUE_FOR_LOST_CARD_LIST, that belongs to queue manager STCD at queue manager level, the appropriate profile would be defined to RACF as:

```
RDEFINE MQQUEUE STCD.QUEUE_FOR_LOST_CARD_LIST
```

This means that different queue managers and queue-sharing groups can share the same RACF database and yet have different security options.

Do not use generic queue manager names in profiles to avoid unanticipated user access.

IBM MQ allows the use of the percent sign (%) in object names. However, RACF uses the % character as a single-character wildcard. This means that when you define an object name with a % character in its name, you must consider this when you define the corresponding profile.

For example, for the queue CREDIT_CARD_%_RATE_INQUIRY, on queue manager CRDP, the profile would be defined to RACF as follows:

```
RDEFINE MQQUEUE CRDP.CREDIT_CARD_%_RATE_INQUIRY
```

This queue cannot be protected by a generic profile, such as, CRDP.**.

IBM MQ allows the use of mixed case characters in object names. You can protect these objects by defining:

1. Mixed case profiles in the appropriate mixed case RACF classes, or
2. Generic profiles in the appropriate uppercase RACF classes.

To use mixed case profiles and mixed case RACF classes you must follow the steps described in z/OS: Migrating a queue manager to mixed case security.

There are some profiles, or parts of profiles, that remain uppercase only as the values are provided by IBM MQ. These are:

- Switch profiles.
- All high-level qualifiers (HLQ) including subsystem and Queue-Sharing Group identifiers.
- Profiles for SYSTEM objects.
- Profiles for Default objects.
- The **MQCMDS** class, so all command profiles are uppercase only.
- The **MQCONN** class, so all connection profiles are uppercase only.
- **RESLEVEL** profiles.

- The `'object'` qualification in command resource profiles; for example, `hlq.QUEUE.queuename`. The resource name only is mixed case.
- Dynamic queue profiles `hlq.CSQOREXX.*`, `hlq.CSQUTIL.*`, and `CSQXCMD.*`.
- The `'CONTEXT '` part of `hlq.CONTEXT.resourcename`.
- The `'ALTERNATE.USER'` part of `hlq.ALTERNATE.USER.userid`.

For example, if you have a queue called `PAYROLL.Dept1` on Queue Manager `QM01` and you are using:
- Mixed case profiles; you can define a profile in the IBM MQ RACF class `MXQUEUE`
  ```
  RDEFINE MXQUEUE MQ01.PAYROLL.Dept1
  ```
- Uppercase profiles; you can define a profile in the IBM MQ RACF class `MQQUEUE`
  ```
  RDEFINE MQQUEUE MQ01.PAYROLL.*
  ```

The first example, using mixed case profiles, gives you more granular control over granting authority to access the resource.

Switch profiles

To control the security checking performed by IBM MQ, you use *switch profiles*. A switch profile is a normal RACF profile that has a special meaning to IBM MQ. The access list in switch profiles is not used by IBM MQ.

IBM MQ maintains an internal switch for each switch type shown in tables Switch profiles for subsystem level security, Switch profiles for queue-sharing group or queue manager level security,and Switch profiles for resource checking. Switch profiles can be maintained at queue-sharing group level, or at queue manager level, or at a combination of both. Using a single set of queue-sharing group security switch profiles, you can control security on all the queue managers within a queue-sharing group.

When a security switch is set on, the security checks associated with the switch are performed. When a security switch is set off, the security checks associated with the switch are bypassed. The default is that all security switches are set on.

Switches and classes

When you start a queue manager or refresh security, IBM MQ sets switches according to the state of various RACF classes.

When a queue manager is started (or when the MQADMIN or MXADMIN class is refreshed by the IBM MQ REFRESH SECURITY command), IBM MQ first checks the status of RACF and the appropriate class:
- The MQADMIN class if you are using uppercase profiles
- The MXADMIN class if you are using mixed case profile.

It sets the subsystem security switch off if any of these conditions is true:
- RACF is inactive or not installed.
- The MQADMIN or MXADMIN class is not defined (these classes are always defined for RACF because they are included in the class descriptor table (CDT)).
- The MQADMIN or MXADMIN class has not been activated.

If both RACF and the MQADMIN or MXADMIN class are active, IBM MQ checks the MQADMIN or MXADMIN class to see whether any of the switch profiles have been defined. It first checks the profiles described in "Profiles to control subsystem security" on page 571. If subsystem security is not required, IBM MQ sets the internal subsystem security switch off, and performs no further checks.

The profiles determine whether the corresponding IBM MQ switch is set on or off.
- If the switch is off, that type of security is deactivated.

- If any IBM MQ switch is set on, IBM MQ checks the status of the RACF class associated with the type of security corresponding to the IBM MQ switch. If the class is not installed or not active, the IBM MQ switch is set off. For example, process security checks are not carried out if the MQPROC or MXPROC class has not been activated. The class not being active is equivalent to defining NO.PROCESS.CHECKS profile for every queue manager and queue-sharing group that uses this RACF database.

How switches work

To set off a security switch, define a NO.* switch profile for it. You can override a NO.* profile set at the queue-sharing group level by defining a YES.* profile for a queue manager.

To set off a security switch, you need to define a NO.* switch profile for it. The existence of a NO.* profile means that security checks are **not** performed for that type of resource, unless you choose to override a queue-sharing group level setting on a particular queue manager. This is described in "Overriding queue-sharing group level settings."

If your queue manager is not a member of a queue-sharing group, you do not need to define any queue-sharing group level profiles or any override profiles. However, you must remember to define these profiles if the queue manager joins a queue-sharing group at a later date.

Each NO.* switch profile that IBM MQ detects turns off the checking for that type of resource. Switch profiles are activated during startup of the queue manager. If you change the switch profiles while any affected queue managers are running, you can get IBM MQ to recognize the changes by issuing the IBM MQ REFRESH SECURITY command.

The switch profiles must always be defined in the MQADMIN or MXADMIN class. Do not define them in the GMQADMIN or GMXADMIN class. Tables Switch profiles for subsystem level security and Switch profiles for resource checking show the valid switch profiles and the security type they control.

Overriding queue-sharing group level settings

You can override queue-sharing group level security settings for a particular queue manager that is a member of that group. If you want to perform queue manager checks on an individual queue manager that are not performed on other queue managers in the group, use the (qmgr-name.YES.*) switch profiles.

Conversely, if you do not want to perform a certain check on one particular queue manager within a queue-sharing group, define a (qmgr-name.NO.*) profile for that particular resource type on the queue manager, and do not define a profile for the queue-sharing group. (IBM MQ only checks for a queue-sharing group level profile if it does not find a queue manager level profile.)

Profiles to control subsystem security

IBM MQ checks whether subsystem security checks are required for the subsystem, for the queue manager, and for the queue-sharing group.

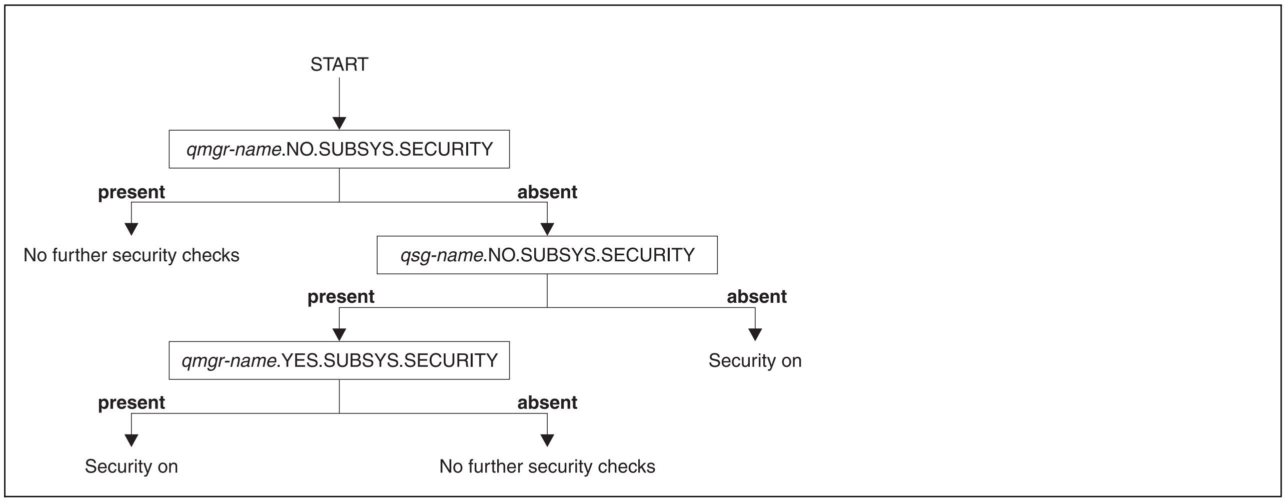
The first security check made by IBM MQ is used to determine whether security checks are required for the whole IBM MQ subsystem. If you specify that you do not want subsystem security, no further checks are made.

The following switch profiles are checked to determine whether subsystem security is required. Figure 67 on page 572 shows the order in which they are checked.

Table 36. Switch profiles for subsystem level security

Switch profile name	Type of resource or checking that is controlled
qmgr-name.NO.SUBSYS.SECURITY	Subsystem security for this queue manager
qsg-name.NO.SUBSYS.SECURITY	Subsystem security for this queue-sharing group
qmgr-name.YES.SUBSYS.SECURITY	Subsystem security override for this queue manager

If your queue manager is not a member of a queue-sharing group, IBM MQ checks for the qmgr-name.NO.SUBSYS.SECURITY switch profile only.



START
qmgr-name.NO.SUBSYS.SECURITY
present
absent
No further security checks
qsg-name.NO.SUBSYS.SECURITY
present
absent
qmgr-name.YES.SUBSYS.SECURITY
Security on
present
absent
Security on
No further security checks

Figure 67. Checking for subsystem security

Profiles to control queue-sharing group or queue manager level security

If subsystem security checking is required, IBM MQ checks whether security checking is required at queue-sharing group or queue manager level.

When IBM MQ has determined that security checking is required, it then determines whether checking is required at queue-sharing group or queue manager level, or both. These checks are not performed if your queue manager is not a member of a queue sharing group.

The following switch profiles are checked to determine the level required. Figure 68 on page 573 and Figure 69 on page 573 show the order in which they are checked.

Table 37. Switch profiles for queue-sharing group or queue manager level security

Switch profile name	Type of resource or checking that is controlled
qmgr-name.NO.QMGR.CHECKS	No queue manager level checks for this queue manager
qsg-name.NO.QMGR.CHECKS	No queue manager level checks for this queue-sharing group
qmgr-name.YES.QMGR.CHECKS	Queue manager level checks override for this queue manager
qmgr-name.NO.QSG.CHECKS	No queue-sharing group level checks for this queue manager
qsg-name.NO.QSG.CHECKS	No queue-sharing group level checks for this queue-sharing group
qmgr-name.YES.QSG.CHECKS	Queue-sharing group level checks override for this queue manager

If subsystem security is active, you cannot switch off both queue-sharing group and queue manager level security. If you try to do so, IBM MQ sets security checking on at both levels.

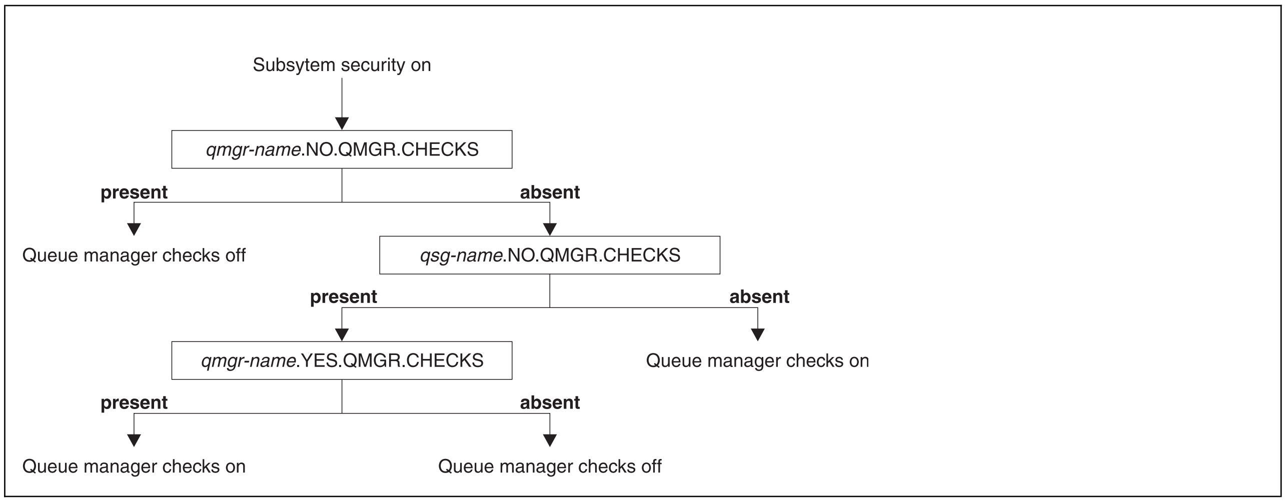


Figure 68. Checking for queue manager level security

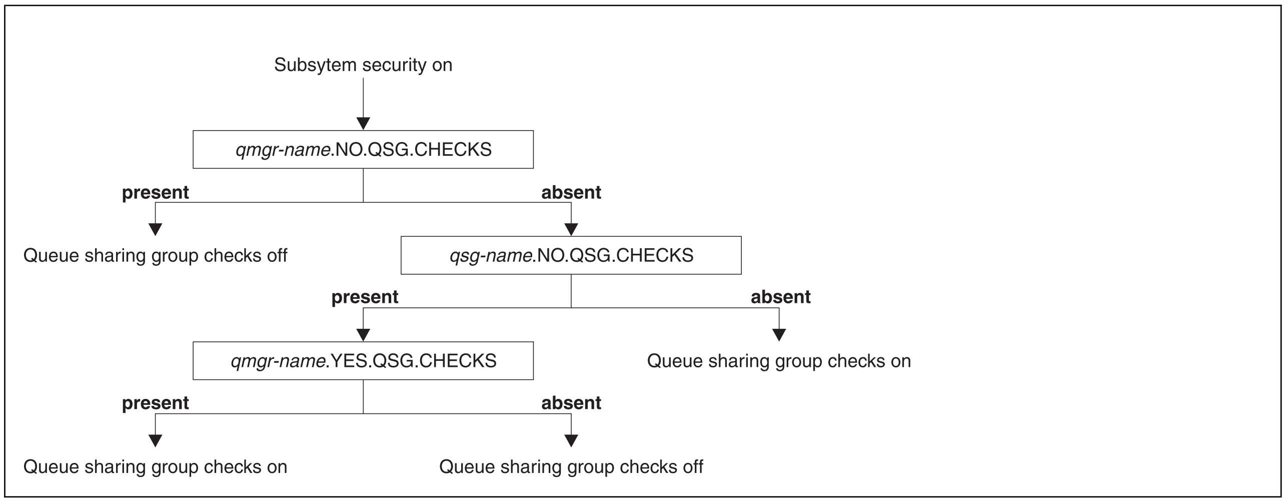

Figure 69. Checking for queue-sharing group level security

Valid combinations of security switches:

Only certain combinations of switches are valid. If you use a combination of switch settings that is not valid, message CSQH026I is issued and security checking is set on at both queue-sharing group and queue manager level.

Table 38, Table 39 on page 574, Table 40 on page 574, and Table 41 on page 574 show the sets of combinations of switch settings that are valid for each type of security level.

Table 38. Valid security switch combinations for queue manager level security

Combinations
qmgr-name.NO.QSG.CHECKS

qmgr-name.NO.QMGR.CHECKS qsg-name.NO.QSG.CHECKS
qsg-name.NO.QMGR.CHECKS qmgr-name.NO.QSG.CHECKS

Resource level checks

A number of switch profiles are used to control access to resources. Some stop checking being performed on either a queue manager or a queue-sharing group. These can be overridden by profiles that enable checking for specific queue managers.

Table 42 shows the switch profiles used to control access to IBM MQ resources.

If your queue manager is part of a queue sharing group and you have both queue manager and queue-sharing group security active, you can use a YES.* switch profile to override queue-sharing group level profiles and specifically turn on security for a particular queue manager.

Some profiles apply to both queue managers and queue-sharing groups. These are prefixed by the string *hlq* and you should substitute the name of your queue-sharing group or queue manager, as applicable. Profile names shown prefixed by *qmgr-name* are queue-manager override profiles; you should substitute the name of your queue manager.

Table 42. Switch profiles for resource checking

Type of resource checking that is controlled	Switch profile name	Override profile for a particular queue manager
Connection security	hlq.NO.CONNECT.CHECKS	qmgr-name.YES.CONNECT.CHECKS
Queue security	hlq.NO.QUEUE.CHECKS	qmgr-name.YES.QUEUE.CHECKS
Process security	hlq.NO.PROCESS.CHECKS	qmgr-name.YES.PROCESS.CHECKS
Namelist security	hlq.NO.NLIST.CHECKS	qmgr-name.YES.NLIST.CHECKS
Context security	hlq.NO.CONTEXT.CHECKS	qmgr-name.YES.CONTEXT.CHECKS
Alternate user security	hlq.NO.ALTERNATE.USER.CHECKS	qmgr-name.YES.ALTERNATE.USER.CHECKS
Command security	hlq.NO.CMD.CHECKS	qmgr-name.YES.CMD.CHECKS
Command resource security	hlq.NO.CMD.RESC.CHECKS	qmgr-name.YES.CMD.RESC.CHECKS
Topic security	hlq.NO.TOPIC.CHECKS	qmgr-name.YES.TOPIC.CHECKS
Note: Generic switch profiles such as hlq.NO.** are ignored by IBM MQ		

For example, if you want to perform process security checks on queue manager QM01, which is a member of queue-sharing group QSG3 but you do not want to perform process security checks on any of the other queue managers in the group, define the following switch profiles:

```
QSG3.NO.PROCESS.CHECKS
QM01.YES.PROCESS.CHECKS
```

If you want to have queue security checks performed on all the queue managers in the queue-sharing group, except QM02, define the following switch profile:

```
QM02.NO.QUEUE.CHECKS
```

(There is no need to define a profile for the queue sharing group because the checks are automatically enabled if there is no profile defined.)

An example of defining switches

Different IBM MQ subsystems have different security requirements, which can be implemented using different switch profiles.

Four IBM MQ subsystems have been defined:

- MQP1 (a production system)
- MQP2 (a production system)
- MQD1 (a development system)
- MQT1 (a test system)

All four queue managers are members of queue-sharing group QS01. All IBM MQ RACF classes have been defined and activated.

These subsystems have different security requirements:

- The production systems require full IBM MQ security checking to be active at queue-sharing group level on both systems.

  This is done by specifying the following profile:

  ```
  RDEFINE MQADMIN QS01.NO.QMGR.CHECKS
  ```

  This sets queue-sharing group level checking for all the queue managers in the queue-sharing group. You do not need to define any other switch profiles for the production queue managers because you want to check everything for these systems.
- Test queue manager MQT1 also requires full security checking. However, because you might want to change this later, security can be defined at queue-manager level so that you can change the security settings for this queue manager without affecting the other members of the queue-sharing group.

  This is done by defining the NO.QSG.CHECKS profile for MQT1 as follows:

  ```
  RDEFINE MQADMIN MQT1.NO.QSG.CHECKS
  ```
- Development queue manager MQD1 has different security requirements from the rest of the queue-sharing group. It requires only connection and queue security to be active.

  This is done by defining a `MQD1.YES.QMGR.CHECKS` profile for this queue manager, and then defining the following profiles to switch off security checking for the resources that do not need to be checked:

  ```
  RDEFINE MQADMIN MQD1.NO.CMD.CHECKS
  RDEFINE MQADMIN MQD1.NO.CMD.RESC.CHECKS
  RDEFINE MQADMIN MQD1.NO.PROCESS.CHECKS
  RDEFINE MQADMIN MQD1.NO.NLIST.CHECKS
  RDEFINE MQADMIN MQD1.NO.CONTEXT.CHECKS
  RDEFINE MQADMIN MQD1.NO.ALTERNATE.USER.CHECKS
  ```

When the queue manager is active, you can display the current security settings by issuing the DISPLAY SECURITY MQSC command.

You can also change the switch settings when the queue manager is running by defining or deleting the appropriate switch profile in the MQADMIN class. To make the changes to the switch settings active, you must issue the REFRESH SECURITY command for the MQADMIN class.

See "Refreshing queue manager security on z/OS" on page 628 for more details about using the DISPLAY SECURITY and REFRESH SECURITY commands.

Profiles used to control access to IBM MQ resources

You must define RACF profiles to control access to IBM MQ resources, in addition to the switch profiles that might have been defined. This collection of topics contains information about the RACF profiles for the different types of IBM MQ resource.

If you do not have a resource profile defined for a particular security check, and a user issues a request that would involve making that check, IBM MQ denies access. You do not have to define profiles for security types relating to any security switches that you have deactivated.

Profiles for connection security

If connection security is active, you must define profiles in the MQCONN class and permit the necessary groups or user IDs access to those profiles, so that they can connect to IBM MQ.

To enable a connection to be made, you must grant users RACF READ access to the appropriate profile. (If no queue manager level profile exists, and your queue manager is a member of a queue-sharing group, checks might be made against queue-sharing group level profiles, if the security is set up to do this.)

A connection profile qualified with a queue manager name controls access to a specific queue manager and users given access to this profile can connect to that queue manager. A connection profile qualified with queue-sharing group name controls access to all queue managers within the queue-sharing group for that connection type. For example, a user with access to `QS01.BATCH` can use a batch connection to any queue manager in queue-sharing group QS01 that has not got a queue manager level profile defined.

Note:

1. For information about the user IDs checked for different security requests, see "User IDs for security checking" on page 617.
2. Resource level security (RESLEVEL) checks are also made at connection time. For details, see "The RESLEVEL security profile" on page 610.

IBM MQ security recognizes the following different types of connection:

- Batch (and batch-type) connections, these include:
  - z/OS batch jobs
  - TSO applications
  - USS sign-ons
  - Db2 stored procedures
- CICS connections
- IMS connections from control and application processing regions
- The IBM MQ channel initiator

Connection security profiles for batch connections:

Profiles for checking batch-type connections are composed of the queue manager or queue-sharing group name followed by the word *BATCH*. Give the user ID associated with the connecting address space READ access to the connection profile.

Profiles for checking batch and batch-type connections take the form:

```
hlq.BATCH
```

where `hlq` can be either the `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name). If you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name. If it does not find one, it looks for a profile prefixed by the queue-sharing group name. If it fails to find either profile, the connection request fails.

For batch or batch-type connection requests, you must permit the user ID associated with the connecting address space to access the connection profile. For example, the following RACF command allows users in the CONNTQM1 group to connect to the queue manager TQM1; these user IDs will be permitted to use any batch or batch-type connection.

```
RDEFINE MQCONN TQM1.BATCH UACC(NONE)
PERMIT TQM1.BATCH CLASS(MQCONN) ID(CONNTQM1) ACCESS(READ)
```

Using **`CHCKLOCL`** *on locally bound applications:*

`CHCKLOCL` only applies to connections that are made through BATCH connections and does not apply to connections made from CICS or IMS. Connections made through the channel initiator are controlled by **`CHCKCLNT`**.

Overview

If you want to configure your z/OS queue manager to mandate user ID and password checking for some, but not all, of your locally bound applications, you need to do some additional configuration.

The reason for this is that once **`CHCKLOCL`** (*REQUIRED*) is configured, legacy batch applications that use the MQCONN API call can no longer connect to the queue manager.

For z/OS only, a more granular mechanism based on the connection security of an address space can be used to downgrade the global CHCKLOCL(REQUIRED) configuration to CHCKLOCL(OPTIONAL) for specifically defined user IDs. The mechanism used, is described in the following text, together with an example.

In order to allow more granularity on **`CHCKLOCL`** (*REQUIRED*) than just EVERYONE, you modify **`CHCKLOCL`** in the same manner as you modify the access level of the user ID associated with the connecting address space to the `hlq.batch` connection profiles in the MQCONN class.

If the address space user ID only has READ access, which is the minimum you require to be able to connect at all, the **`CHCKLOCL`** configuration applies as written.

If the address space user ID has UPDATE access (or above) then the **`CHCKLOCL`** configuration operates in *OPTIONAL* mode. That is, you do not have to provide a user ID and password, but if you do, the user ID and password must be a valid pair.

Connection security already configured for your z/OS queue manager

If you have connection security configured for your z/OS queue manager and you want **`CHCKLOCL`** (*REQUIRED*) to apply to WAS locally bound applications, and no others, carry out the following steps:

1. Start with **CHCKLOCL** (*OPTIONAL*) as your configuration. This means that any user ID and passwords that are supplied are checked for validity, but not mandated.
2. List all the users that have access to the connection security profiles by issuing the command:
   ```
   RLIST MQCONN MQ23.BATCH AUTHUSER
   ```
   This command displays, for example:
   ```
   CLASS    NAME
   -----    ----
   MQCONN   MQ23.BATCH

   USER     ACCESS  ACCESS COUNT
   ----     ------  ------ -----
   JOHNDOE  READ    000009
   JDOE1    READ    000003
   WASUSER  READ    000000
   ```
3. For each user ID listed as having READ access, change the access to
   ```
   UPDATE:- PERMIT MQ23.BATCH CLASS(MQCONN) ID(JOHNDOE) ACCESS(UPDATE)
   ```
4. Update the IBM MQ configuration to **CHCKLOCL** (*REQUIRED*).

   The combination of UPDATE access to `MQ23.BATCH` and the current setting means that you are using **CHCKLOCL** (*OPTIONAL*).
5. Now, apply the **CHCKLOCL** (*REQUIRED*) behavior to one specific user ID, for example `WASUSER`, so that all the connections coming from that region must provide a user ID and password.
6. Do this by reversing the change you made previously, by issuing the command:
   ```
   PERMIT MQ23.BATCH CLASS(MQCONN) ID(WASUSER) ACCESS(READ)
   ```

Connection security is not configured for your z/OS queue manager

In this situation, you must:
1. Create connection profiles for `hlq.BATCH` in the MQCONN class, by issuing the command:
   ```
   RDEFINE MQCONN MQ23.BATCH UACC(NONE)
   ```
2. Authorize all user IDs that create batch connections to the queue manager, so that they have UPDATE access to this profile. Doing this bypasses the **CHCKLOCL** (*REQUIRED*) requirement for the user ID and password at the time of connection.
3. Do this by issuing the command:
   ```
   PERMIT MQ23.BATCH CLASS(MQCONN)ID(JOHNDOE) ACCESS(UPDATE)
   ```
   These include user IDs:
   a. Used for CSQUTIL, ISPF panels, and other locally bound tools.
   b. Associated with batch like connections to the queue manager. Consider for example, IBM MQ Advanced Message Security, IBM Integration Bus, Db2 stored procedures, USS and TSO users, and Java applications
4. Delete the switch profile for the queue manager by issuing the command:
   ```
   hlq.NO.CONNECT.CHECKS
   ```
5. Now, apply the **CHCKLOCL** (*REQUIRED*) behavior to one specific user ID, for example `WASUSER`, so that all the connections coming from that region must provide a user ID and password.
6. Do this by reversing the change you made previously, by issuing the command:
   ```
   PERMIT MQ23.BATCH CLASS(MQCONN) ID(WASUSER) ACCESS(READ)
   ```

Connection security profiles for CICS connections:

Profiles for checking CICS connections are composed of the queue manager or queue-sharing group name followed by the word *CICS* . Give the user ID associated with the CICS address space READ access to the connection profile.

Profiles for checking connections from CICS take the form:

```
hlq.CICS
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name). If you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name. If it does not find one, it looks for a profile prefixed by the queue-sharing group name. If it fails to find either profile, the connection request fails

For connection requests by CICS, you need only permit the CICS address space user ID access to the connection profile.

For example, the following RACF commands allow the CICS address space user ID KCBCICS to connect to the queue manager TQM1:

```
RDEFINE MQCONN TQM1.CICS UACC(NONE)
PERMIT TQM1.CICS CLASS(MQCONN) ID(KCBCICS) ACCESS(READ)
```

Connection security profiles for IMS connections:

Profiles for checking IMS connections are composed of the queue manager or queue-sharing group name followed by the word *IMS* . Give the IMS control and dependent region user IDs READ access to the connection profile.

Profiles for checking connections from IMS take the form:

```
hlq.IMS
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name). If you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name. If it does not find one, it looks for a profile prefixed by the queue-sharing group name. If it fails to find either profile, the connection request fails

For connection requests by IMS, permit access to the connection profile for the IMS control and dependent region user IDs.

For example, the following RACF commands allow:
- The IMS region user ID, IMSREG, to connect to the queue manager TQM1.
- Users in group BMPGRP to submit BMP jobs.

```
RDEFINE MQCONN TQM1.IMS UACC(NONE)
PERMIT TQM1.IMS CLASS(MQCONN) ID(IMSREG,BMPGRP) ACCESS(READ)
```

Connection security profiles for the channel initiator:

Profiles for checking connections from the channel initiator are composed of the queue manager or queue-sharing group name followed by the word *CHIN*. Give the user ID used by the channel initiator started task address space READ access to the connection profile.

Profiles for checking connections from the channel initiator take the form:

```
hlq.CHIN
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name). If you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name. If it does not find one, it looks for a profile prefixed by the queue-sharing group name. If it fails to find either profile, the connection request fails

For connection requests by the channel initiator, define access to the connection profile for the user ID used by the channel initiator started task address space.

For example, the following RACF commands allow the channel initiator address space running with user ID DQCTRL to connect to the queue manager TQM1:

```
RDEFINE MQCONN TQM1.CHIN UACC(NONE)
PERMIT TQM1.CHIN CLASS(MQCONN) ID(DQCTRL) ACCESS(READ)
```

Profiles for queue security

If queue security is active, you must define profiles in the appropriate classes and permit the necessary groups or user IDs access to these profiles. Queue security profiles are named after the queue manager or queue-sharing group, and the queue to be opened.

If queue security is active, you must:

- Define profiles in the **`MQQUEUE`** or **`GMQQUEUE`** classes if using uppercase profiles.
- Define profiles in the **`MXQUEUE`** or **`GMXQUEUE`** classes if using mixed case profiles.
- Permit the necessary groups or user IDs access to these profiles, so that they can issue IBM MQ API requests that use queues.

Profiles for queue security take the form:

```
hlq.queuename
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name), and `queuename` is the name of the queue being opened, as specified in the object descriptor on the **MQOPEN** or **MQPUT1** call.

A profile prefixed by the queue manager name controls access to a single queue on that queue manager. A profile prefixed by the queue-sharing group name controls access to access to one or more queues with that queue name on all queue managers within the queue-sharing group, or access to a shared queue by any queue manager within the group. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that queue on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

If you are using shared queues, you are recommended to use queue-sharing group level security.

For details of how queue security operates when the queue name is that of an alias or a model queue z/OS, see "Considerations for alias queues" on page 584 and "Considerations for model queues" on page 585.

The RACF access required to open a queue depends on the **MQOPEN** or **MQPUT1** options specified. If more than one of the MQOO_* and MQPMO_* options is coded, the queue security check is performed for the highest RACF authority required.

Table 43. Access levels for queue security using the MQOPEN or MQPUT1 calls

MQOPEN or MQPUT1 option	RACF access level required to access hlq.queuename
MQOO_BROWSE	READ
MQOO_INQUIRE	READ
MQOO_BIND_*	UPDATE
MQOO_INPUT_*	UPDATE
MQOO_OUTPUT or MQPUT1	UPDATE
MQOO_PASS_ALL_CONTEXT MQPMO_PASS_ALL_CONTEXT	UPDATE
MQOO_PASS_IDENTITY_CONTEXT MQPMO_PASS_IDENTITY_CONTEXT	UPDATE
MQOO_SAVE_ALL_CONTEXT	UPDATE
MQOO_SET_IDENTITY_CONTEXT MQPMO_SET_IDENTITY_CONTEXT	UPDATE
MQOO_SET_ALL_CONTEXT MQPMO_SET_ALL_CONTEXT	UPDATE
MQOO_SET	ALTER

For example, on IBM MQ queue manager QM77, all user IDs in the RACF group PAYGRP are to be given access to get messages from or put messages to all queues with names beginning with 'PAY.'. You can do this using these RACF commands:

```
RDEFINE MQQUEUE QM77.PAY.** UACC(NONE)
PERMIT QM77.PAY.** CLASS(MQQUEUE) ID(PAYGRP) ACCESS(UPDATE)
```

Also, all user IDs in the PAYGRP group must have access to put messages on queues that do not follow the PAY naming convention. For example:

```
REQUEST_QUEUE_FOR_PAYROLL
SALARY.INCREASE.SERVER
REPLIES.FROM.SALARY.MODEL
```

You can do this by defining profiles for these queues in the GMQQUEUE class and giving access to that class as follows:

```
RDEFINE GMQQUEUE PAYROLL.EXTRAS UACC(NONE)
        ADDMEM(QM77.REQUEST_QUEUE_FOR_PAYROLL,
               QM77.SALARY.INCREASE.SERVER,
               QM77.REPLIES.FROM.SALARY.MODEL)
PERMIT PAYROLL.EXTRAS CLASS(GMQQUEUE) ID(PAYGRP) ACCESS(UPDATE)
```

Note:

1. If the RACF access level that an application has to a queue security profile is changed, the changes only take effect for any new object handles obtained (that is, new **MQOPEN** s) for that queue. Those handles already in existence at the time of the change retain their existing access to the queue. If an application is required to use its changed access level to the queue rather than its existing access level, it must close and reopen the queue for each object handle that requires the change.
2. In the example, the queue manager name `QM77` could also be the name of a queue-sharing group.

Other types of security checks might also occur at the time the queue is opened depending on the open options specified and the types of security that are active. z/OS See also "Profiles for context security" on page 598 and "Profiles for alternate user security" on page 596. For a summary table showing the open options and the security authorization needed when queue, context, and alternate user security are all active, see Table 48 on page 589.

If you are using publish/subscribe you must consider the following. When an MQSUB request is processed a security check is performed to ensure that the user ID making the request has the required access to put messages to the target IBM MQ queue as well as the required access to subscribe to the IBM MQ topic.

Table 44. Access levels for queue security using the MQSUB call

MQSUB option	RACF access level required to access hlq.queuename
MQSO_ALTER, MQSO_CREATE, and MQSO_RESUME	UPDATE

Note:

1. The `hlq.queuename` is the destination queue for publications. When this is a managed queue, you need access to the appropriate model queue to be used for the managed queue and the dynamic queue that are created.
2. You can use a technique like this for the destination queue you provide on an MQSUB API call if you want to distinguish between the users making the subscriptions, and the users retrieving the publications from the destination queue.

Considerations for alias queues:

When you issue an **MQOPEN** or **MQPUT1** call for an alias queue, IBM MQ makes a resource check against the queue name specified in the object descriptor (MQOD) on the call. It does not check if the user is allowed access to the target queue name.

For example, an alias queue called PAYROLL.REQUEST resolves to a target queue of PAY.REQUEST. If queue security is active, you need only be authorized to access the queue PAYROLL.REQUEST. No check is made to see if you are authorized to access the queue PAY.REQUEST.

Using alias queues to distinguish between MQGET and MQPUT requests:

The range of MQI calls available in one access level can cause a problem if you want to restrict access to a queue to allow only the **MQPUT** call or only the **MQGET** call. A queue can be protected by defining two aliases that resolve to that queue: one that enables applications to get messages from the queue, and one that enable applications to put messages on the queue.

The following text gives you an example of how you can define your queues to IBM MQ:

```
DEFINE QLOCAL(MUST_USE_ALIAS_TO_ACCESS) GET(ENABLED)
       PUT(ENABLED)

DEFINE QALIAS(USE_THIS_ONE_FOR_GETS) GET(ENABLED)
       PUT(DISABLED) TARGQ(MUST_USE_ALIAS_TO_ACCESS)

DEFINE QALIAS(USE_THIS_ONE_FOR_PUTS) GET(DISABLED)
       PUT(ENABLED) TARGQ(MUST_USE_ALIAS_TO_ACCESS)
```

You must also make the following RACF definitions:

```
RDEFINE MQQUEUE hlq.MUST_USE_ALIAS_TO_ACCESS UACC(NONE)
RDEFINE MQQUEUE hlq.USE_THIS_ONE_FOR_GETS UACC(NONE)
RDEFINE MQQUEUE hlq.USE_THIS_ONE_FOR_PUTS UACC(NONE)
```

Then you ensure that no users have access to the queue hlq.MUST_USE_ALIAS_TO_ACCESS, and give the appropriate users or groups access to the alias. You can do this using the following RACF commands:

```
PERMIT hlq.USE_THIS_ONE_FOR_GETS CLASS(MQQUEUE)
       ID(GETUSER,GETGRP) ACCESS(UPDATE)
PERMIT hlq.USE_THIS_ONE_FOR_PUTS CLASS(MQQUEUE)
       ID(PUTUSER,PUTGRP) ACCESS(UPDATE)
```

This means user ID GETUSER and user IDs in the group GETGRP are only allowed to get messages on MUST_USE_ALIAS_TO_ACCESS through the alias queue USE_THIS_ONE_FOR_GETS; and user ID PUTUSER and user IDs in the group PUTGRP are only allowed to put messages through the alias queue USE_THIS_ONE_FOR_PUTS.

Note:

1. If you want to use a technique like this, you must inform your application developers, so that they can design their programs appropriately.
2. You can use a technique like this for the destination queue you provide on and MQSUB API request if you want to distinguish between the users making the subscriptions and the users 'getting' the publications from the destination queue.

Considerations for model queues:

To open a model queue, you must be able to open both the model queue itself and the dynamic queue to which it resolves. Define generic RACF profiles for dynamic queues, including dynamic queues used by IBM MQ utilities.

When you open a model queue, IBM MQ security makes two queue security checks:

1. Are you authorized to access the model queue?
2. Are you authorized to access the dynamic queue to which the model queue resolves?

If the dynamic queue name contains a trailing asterisk (*) character, this * is replaced by a character string generated by IBM MQ, to create a dynamic queue with a unique name. However, because the whole name, including this generated string, is used for checking authority, you should define generic profiles for these queues.

For example, an **MQOPEN** call uses a model queue name of CREDIT.CHECK.REPLY.MODEL and a dynamic queue name of CREDIT.REPLY.* on queue manager (or queue-sharing group) MQSP.

To do this, you must issue the following RACF commands to define the necessary queue profiles:

```
RDEFINE MQQUEUE MQSP.CREDIT.CHECK.REPLY.MODEL
RDEFINE MQQUEUE MQSP.CREDIT.REPLY.**
```

You must also issue the corresponding RACF PERMIT commands to allow the user access to these profiles.

A typical dynamic queue name created by an **MQOPEN** is something like CREDIT.REPLY.A346EF00367849A0. The precise value of the last qualifier is unpredictable; this is why you should use generic profiles for such queue names.

A number of IBM MQ utilities put messages on dynamic queues. You should define profiles for the following dynamic queue names, and provide RACF UPDATE access to the relevant user IDs (see “User IDs for security checking” on page 617 for the correct user IDs):

```
SYSTEM.CSQUTIL.*  (used by CSQUTIL)
SYSTEM.CSQOREXX.* (used by the operations and control panels)
SYSTEM.CSQXCMD.*  (used by the channel initiator when processing CSQINPX)
CSQ4SAMP.*        (used by the WebSphere MQ supplied samples)
```

You might also consider defining a profile to control use of the dynamic queue name used by default in the application programming copy members. The IBM MQ-supplied copybooks contain a default *DynamicQName*, which is CSQ.*. This enables an appropriate RACF profile to be established.

Note: Do not allow application programmers to specify a single * for the dynamic queue name. If you do, you must define an hlq.** profile in the MQQUEUE class, and you would have to give it wide-ranging access. This means that this profile could also be used for other non-dynamic queues that do not have a more specific RACF profile. Your users could, therefore, gain access to queues you do not want them to access.

Close options on permanent dynamic queues:

If an application opens a permanent dynamic queue that was created by another application and then attempts to delete that queue with an **MQCLOSE** option, some extra security checks are applied when the attempt is made.

Table 45. Access levels for close options on permanent dynamic queues

MQCLOSE option	RACF access level required to hlq.queuename
MQCO_DELETE	ALTER
MQCO_DELETE_PURGE	ALTER

Security and remote queues:

When a message is put on a remote queue, the queue security that is implemented by the local queue manager depends on how the remote queue is specified when it is opened.

The following rules are applied:

1. If the remote queue has been defined on the local queue manager through the IBM MQ DEFINE QREMOTE command, the queue that is checked is the name of the remote queue. For example, if a remote queue is defined on queue manager MQS1 as follows:
   ```
   DEFINE QREMOTE(BANK7.CREDIT.REFERENCE)
          RNAME(CREDIT.SCORING.REQUEST)
          RQMNAME(BNK7)
          XMITQ(BANK1.TO.BANK7)
   ```
   In this case, a profile for BANK7.CREDIT.REFERENCE must be defined in the MQQUEUE class.
2. If the *ObjectQMgrName* for the request does not resolve to the local queue manager, a security check is carried out against the resolved (remote) queue manager name except in the case of a cluster queue where the check is made against the cluster queue name.

   For example, the transmission queue BANK1.TO.BANK7 is defined on queue manager MQS1. An **MQPUT1** request is then issued on MQS1 specifying *ObjectName* as BANK1.INTERBANK.TRANSFERS and an *ObjectQMgrName* of BANK1.TO.BANK7. In this case, the user performing the request must have access to BANK1.TO.BANK7.
3. If you make an **MQPUT** request to a queue and specify `ObjectQMgrName` as the name of an alias of the local queue manager, only the queue name is checked for security, not that of the queue manager.

When the message gets to the remote queue manager it might be subject to additional security processing. For more information, see "Security for remote messaging" on page 463.

Dead-letter queue security:

Special considerations apply to the dead-letter queue, because many users must be able to put messages on it, but access to retrieve messages must be tightly restricted. You can achieve this by applying different RACF authorities to the dead-letter queue and an alias queue.

Undelivered messages can be put on a special queue called the dead-letter queue. If you have sensitive data that could possibly end up on this queue, you must consider the security implications of this because you do not want unauthorized users to retrieve this data.

Each of the following must be allowed to put messages onto the dead-letter queue:
- Application programs.
- The channel initiator address space and any MCA user IDs. (If the RESLEVEL profile is not present, or is defined so that channel user IDs are checked, the channel user ID also needs authority to put messages on the dead-letter queue.)
- CKTI, the IBM MQ-supplied CICS task initiator.
- CSQQTRMN, the IBM MQ-supplied IMS trigger monitor.

The only application that can retrieve messages from the dead-letter queue should be a 'special' application that processes these messages. However, a problem arises if you give applications RACF UPDATE authority to the dead-letter queue for **MQPUT** s because they can then automatically retrieve messages from the queue using **MQGET** calls. You cannot disable the dead-letter queue for get operations because, if you do, not even the 'special' applications could retrieve the messages.

One solution to this problem is set up a two-level access to the dead-letter queue. CKTI, message channel agent transactions or the channel initiator address space, and 'special' applications have direct access; other applications can only access the dead-letter queue through an alias queue. This alias is defined to allow applications to put messages on the dead-letter queue, but not to get messages from it.

This is how it might work:
1. Define the real dead-letter queue with attributes PUT(ENABLED) and GET(ENABLED), as shown in the sample thlqual.SCSQPROC(CSQ4INYG).
2. Give RACF UPDATE authority for the dead-letter queue to the following user IDs:
   - User IDs that the CKTI and the MCAs or channel initiator address space run under.
   - The user IDs associated with the 'special' dead-letter queue processing application.
3. Define an alias queue that resolves to the real dead-letter queue, but give the alias queue these attributes: PUT(ENABLED) and GET(DISABLED). Give the alias queue a name with the same stem as the dead-letter queue name but append the characters ".PUT" to this stem. For example, if the dead-letter queue name is hlq.DEAD.QUEUE, the alias queue name would be hlq.DEAD.QUEUE.PUT.
4. To put a message on the dead-letter queue, an application uses the alias queue. This is what your application must do:
   - Retrieve the name of the real dead-letter queue. To do this, it opens the queue manager object using **MQOPEN** and then issues an **MQINQ** to get the dead-letter queue name.
   - Build the name of the alias queue by appending the characters '.PUT' to this name, in this case, hlq.DEAD.QUEUE.PUT.
   - Open the alias queue, hlq.DEAD.QUEUE.PUT.
   - Put the message on the real dead-letter queue by issuing an **MQPUT** against the alias queue.
5. Give the user ID associated with the application RACF UPDATE authority to the alias, but no access (authority NONE) to the real dead-letter queue. This means that:
   - The application can put messages onto the dead-letter queue using the alias queue.
   - The application cannot get messages from the dead-letter queue using the alias queue because the alias queue is disabled for get operations.

The application cannot get any messages from the real dead-letter queue either because it does have the correct RACF authority.

Table 46 summarizes the RACF authority required for the various participants in this solution.

Table 46. RACF authority to the dead-letter queue and its alias

Associated user IDs	**Real dead-letter queue (hlq.DEAD.QUEUE)**	**Alias dead-letter queue (hlq.DEAD.QUEUE.PUT)**
MCA or channel initiator address space and CKTI	UPDATE	NONE
'Special' application (for dead-letter queue processing)	UPDATE	NONE
User-written application user IDs	NONE	UPDATE

If you use this method, the application cannot determine the maximum message length (MAXMSGL) of the dead-letter queue. This is because the MAXMSGL attribute cannot be retrieved from an alias queue. Therefore, your application should assume that the maximum message length is 100 MB, the maximum size IBM MQ for z/OS supports. The real dead-letter queue should also be defined with a MAXMSGL attribute of 100 MB.

Note: User-written application programs do not normally use alternate user authority to put messages on the dead-letter queue. This reduces the number of user IDs that have access to the dead-letter queue.

System queue security:

You must set up RACF access to allow certain user IDs access to particular system queues.

Many of the system queues are accessed by the ancillary parts of IBM MQ:
- The CSQUTIL utility
- The operations and control panels
- The channel initiator address space (including the Queued Pub/Sub Daemon)

The user IDs under which these run must be given RACF access to these queues, as shown in Table 47.

Table 47. Access required to the SYSTEM queues by IBM MQ

SYSTEM queue	**CSQUTIL**		**Operations and control panels**	**Channel initiator for distributed queuing**
SYSTEM.ADMIN.CHANNEL.EVENT	-	-	-	UPDATE

MQSUB option				
MQSO_CREATE	ALTER **(15)**	**(17)**	**(18)**	
MQSO_ALTER	ALTER **(15)**	**(17)**	**(18)**	
MQSO_RESUME	READ **(15)**	**(17)**	No check	
MQSO_ALTERNATE_USER_AUTHORITY				UPDATE
MQSO_SET_IDENTITY_CONTEXT			**(18)**	

Note:

1. This option is not restricted to queues. Use the MQNLIST or MXNLIST class for namelists, and the MQPROC or MXPROC class for processes.
2. Use RACF profile: hlq.resourcename
3. Use RACF profile: hlq.CONTEXT.queuename
4. Use RACF profile: hlq.ALTERNATE.USER. `alternateuserid`

   `alternateuserid` is the user identifier that is specified in the *AlternateUserId* field of the object descriptor. Note that up to 12 characters of the *AlternateUserId* field are used for this check, unlike other checks where only the first 8 characters of a user identifier are used.
5. No check is made when opening the queue manager for inquiries.
6. MQOO_INPUT_* must be specified as well. This is valid for a local, model or alias queue.
7. This check is done for a local or model queue that has a *Usage* queue attribute of MQUS_NORMAL, and also for an alias or remote queue (that is defined to the connected queue manager.) If the queue is a remote queue that is opened specifying an *ObjectQMgrName* (not the name of the connected queue manager) explicitly, the check is carried out against the queue with the same name as *ObjectQMgrName* (which must be a local queue with a *Usage* queue attribute of MQUS_TRANSMISSION).
8. MQOO_OUTPUT must be specified as well.

9. MQOO_PASS_IDENTITY_CONTEXT is implied as well by this option.
10. MQOO_PASS_IDENTITY_CONTEXT, MQOO_PASS_ALL_CONTEXT and MQOO_SET_IDENTITY_CONTEXT are implied as well by this option.
11. This check is done for a local or model queue that has a *Usage* queue attribute of MQUS_TRANSMISSION, and is being opened directly for output. It does not apply if a remote queue is being opened.
12. At least one of MQOO_INQUIRE, MQOO_BROWSE, MQOO_INPUT_*, MQOO_OUTPUT or MQOO_SET must be specified as well. The check carried out is the same as that for the other options specified.
13. The check carried out is the same as that for the other options specified.
14. This applies only for permanent dynamic queues that have been opened directly, that is, not opened through a model queue. No security is required to delete a temporary dynamic queue.
15. Use RACF profile hlq.SUBSCRIBE.topicname.
16. Use RACF profile hlq.PUBLISH.topicname.
17. If on the MQSUB request you specified a destination queue for the publications to be sent to, then a security check is carried out against that queue to ensure that you have put authority to that queue.
18. If on the MQSUB request, with MQSO_CREATE or MQSO_ALTER options specified, you want to set any of the identity context fields in the MQSD structure, you also need to specify the MQSO_SET_IDENTITY_CONTEXT option and you also need the appropriate authority to the context profile for the destination queue.

Profiles for topic security

If topic security is active, you must define profiles in the appropriate classes and permit the necessary groups or user IDs access to those profiles.

The concept of topic security within a topic tree is described in Publish/subscribe security.

If topic security is active, you must perform the following actions:
- Define profiles in the **MXTOPIC** or **GMXTOPIC** classes.
- Permit the necessary groups or user IDs access to these profiles, so that they can issue IBM MQ API requests that use topics.

Profiles for topic security take the form:

```
hlq.SUBSCRIBE.topicname
hlq.PUBLISH.topicname
```

where
- `hlq` is either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name).
- `topicname` is the name of the topic administration node in the topic tree, associated either with the topic being subscribed to through an MQSUB call, or being published to through an MQOPEN call.

A profile prefixed by the queue manager name controls access to a single topic on that queue manager. A profile prefixed by the queue-sharing group name controls access to one or more topics with that topic name on all queue managers within the queue-sharing group. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that topic on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

Subscribe

To subscribe to a topic, you need access to both the topic you are trying to subscribe to, and the target queue for the publications.

When you issue an MQSUB request, the following security checks take place:
- Whether you have the appropriate level of access to subscribe to that topic, and also that the target queue (if specified) is opened for output
- Whether you have the appropriate level of access to that target queue.

Table 49. Access level required for topic security to subscribe

Action	**Access level required**
MQSUB to a topic	RACF access required to `hlq.SUBSCRIBE.topicname` profile in MXTOPIC class
MQSO_CREATE and MQSO_ALTER	ALTER
MQSO_RESUME	READ
MQSUB - additional authority to non-managed destination queues.	RACF access required to `hlq.CONTEXT.queuename` profile in MQADMIN or MXADMIN class
MQSO_CREATE, MQSO_ALTER, and MQSO_RESUME	UPDATE
	RACF access required to `hlq.queuename` profile in MQQUEUE or MXQUEUE class
MQSO_CREATE and MQSO_ALTER	UPDATE
	RACF access required to `hlq.ALTERNATE.USER.alternateuserid` profile in MQADMIN or MXADMIN class
MQSO_ALTERNATE_USER_AUTHORITY	UPDATE

Considerations for managed queues for subscriptions

A security check is carried out to see if you are allowed to subscribe to the topic. However, no security checks are carried out when the managed queue is created, or to determine if you have access to put messages to this destination queue.

You cannot close delete a managed queue.

The model queues used are: `SYSTEM.DURABLE.MODEL.QUEUE` and `SYSTEM.NDURABLE.MODEL.QUEUE`.

The managed queues created from these model queues are of the form `SYSTEM.MANAGED.DURABLE.A346EF00367849A0` and `SYSTEM.MANAGED.NDURABLE.A346EF0036785EA0` where the last qualifier is unpredictable.

Do not give any user access to these queues. The queues can be protected using generic profiles of the form `SYSTEM.MANAGED.DURABLE.*` and `SYSTEM.MANAGED.NDURABLE.*` with no authorities granted.

Messages can be retrieved from these queues using the handle returned on the MQSUB request.

If you explicitly issue an MQCLOSE call for a subscription with the MQCO_REMOVE_SUB option specified, and you did not create the subscription you are closing under this handle, a security check is performed at the time of closure to ensure that you have the correct authority to perform the operation.

Table 50. Access level required to profiles for topic security for closure of a subscribe operation

Action	Access level required
MQCLOSE (of a subscription)	RACF access required to *hlq.SUBSCRIBE.topicname* profile in MXTOPIC class
MQCO_REMOVE_SUB	ALTER

Publish

To publish on a topic you need access to the topic and, if you are using alias queues, to the alias queue as well.

Table 51. Access level required to profiles for topic security for a publish operation

Action	Access level required
MQOPEN (of a topic)	RACF access required to *hlq.PUBLISH.topicname* profile in MXTOPIC class
MQOO_OUTPUT or MQPUT1	UPDATE
MQOPEN (Alias queue to topic)	RACF access required to *hlq.queuename* profile in MQQUEUE or MXQUEUE class for the alias queue
MQOO_OUTPUT or MQPUT1	UPDATE

For details of how topic security operates when an alias queue that resolves to a topic name is opened for publish, see "Considerations for alias queues that resolve to topics for a publish operation."

When you consider alias queues used for destination queues for PUT or GET restrictions, see "Considerations for alias queues" on page 584.

If the RACF access level that an application has to a topic security profile is changed, the changes take effect only for any new object handles obtained (that is, a new MQSUB or MQOPEN) for that topic. Those handles already in existence at the time of the change retain their existing access to the topic. Also, existing subscribers retain their access to any subscriptions that they have already made.

Considerations for alias queues that resolve to topics for a publish operation

When you issue an MQOPEN or MQPUT1 call for an alias queue that resolves to a topic, IBM MQ makes two resource checks:

- The first one against the alias queue name specified in the object descriptor (MQOD) on the MQOPEN or MQPUT1 call.
- The second against the topic to which the alias queue resolves

You must be aware that this behavior is different from the behavior you get when alias queues resolve to other queues. You need the correct access to both profiles in order for the publish action to proceed.

System topic security

Many of the system topics are accessed by the ancillary parts of IBM MQ, for example the channel initiator address space.

The user IDs under which this runs must be given RACF access to these queues, as shown in Table 52 on page 594.

Table 52. Access required to the SYSTEM topics

SYSTEM topic	Profile	Channel Initiator for Distributed queuing
SYSTEM.BROKER.ADMIN.STREAM	PUBLISH.topicname	UPDATE
SYSTEM.BROKER.ADMIN.STREAM	SUBSCRIBE.topicname	ALTER

Profiles for processes

If process security is active, you must define profiles in the appropriate classes and permit the necessary groups or user IDs access to those profiles.

If process security is active, you must:

- Define profiles in the **MQPROC** or **GMQPROC** classes if using uppercase profiles.
- Define profiles in the **MXPROC** or **GMXPROC** classes if using mixed case profiles.
- Permit the necessary groups or user IDs access to these profiles, so that they can issue IBM MQ API requests that use processes.

Profiles for processes take the form:

```
hlq.processname
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name), and `processname` is the name of the process being opened.

A profile prefixed by the queue manager name controls access to a single process definition on that queue manager. A profile prefixed by the queue-sharing group name controls access to one or more process definitions with that name on all queue managers within the queue-sharing group. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that process definition on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

The following table shows the access required for opening a process.

Table 53. Access levels for process security

MQOPEN option	RACF access level required to hlq.processname
MQOO_INQUIRE	READ

For example, on queue manager MQS9, the RACF group INQVPRC must be able to inquire (**MQINQ**) on all processes starting with the letter V. The RACF definitions for this would be:

```
RDEFINE MQPROC MQS9.V* UACC(NONE)
PERMIT MQS9.V* CLASS(MQPROC) ID(INQVPRC) ACCESS(READ)
```

Alternate user security might also be active, depending on the open options specified when a process definition object is opened.

Profiles for namelists

If namelist security is active, you define profiles in the appropriate classes and give the necessary groups or user IDs access to these profiles.

If namelist security is active, you must:

- Define profiles in the **MQNLIST** or **GMQNLIST** classes if using uppercase profiles.
- Define profiles in the **MXNLIST** or **GMXNLIST** classes if using mixed case profiles.
- Permit the necessary groups or user IDs access to these profiles.

Profiles for namelists take the form:

```
hlq.namelistname
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name), and `namelistname` is the name of the namelist being opened.

A profile prefixed by the queue manager name controls access to a single namelist on that queue manager. A profile prefixed by the queue-sharing group name controls access to access to one or more namelists with that name on all queue managers within the queue-sharing group. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that namelist on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

The following table shows the access required for opening a namelist.

Table 54. Access levels for namelist security

MQOPEN option	RACF access level required to hlq.namelistname
MQOO_INQUIRE	READ

For example, on queue manager (or queue-sharing group) PQM3, the RACF group DEPT571 must be able to inquire (**MQINQ**) on these namelists:

- All namelists starting with "DEPT571".
- PRINTER/DESTINATIONS/DEPT571
- AGENCY/REQUEST/QUEUES
- WAREHOUSE.BROADCAST

The RACF definitions to do this are:

```
RDEFINE MQNLIST PQM3.DEPT571.** UACC(NONE)
PERMIT PQM3.DEPT571.** CLASS(MQNLIST) ID(DEPT571) ACCESS(READ)

RDEFINE GMQNLIST NLISTS.FOR.DEPT571 UACC(NONE)
        ADDMEM(PQM3.PRINTER/DESTINATIONS/DEPT571,
               PQM3.AGENCY/REQUEST/QUEUES,
               PQM3.WAREHOUSE.BROADCAST)
PERMIT NLISTS.FOR.DEPT571 CLASS(GMQNLIST) ID(DEPT571) ACCESS(READ)
```

Alternate user security might be active, depending on the options specified when a namelist object is opened.

System namelist security

Many of the system namelists are accessed by the ancillary parts of IBM MQ:
- The CSQUTIL utility
- The operations and control panels
- The channel initiator address space (including the Queued Publish/Subscribe Daemon)

The user IDs under which these run must be given RACF access to these namelists, as shown in Table 55.

Table 55. Access required to the SYSTEM namelists by IBM MQ

SYSTEM namelist	CSQUTIL	Operations and control panels	Channel initiator for distributed queuing
SYSTEM.QPUBSUB.QUEUE.NAMELIST	-	-	READ
SYSTEM.QPUBSUB.SUBPOINT.NAMELIST	-	-	READ

Profiles for alternate user security

If alternate user security is active, you must define profiles in the appropriate classes and permit the necessary groups or user IDs access to those profiles.

For more information about *AlternateUserId*, see AlternateUserID (MQCHAR12).

If alternate user security is active, you must:
- Define profiles in the MQADMIN or GMQADMIN classes if you are using uppercase profiles.
- Define profiles in the MXADMIN or GMXADMIN classes if you are using mixed case profiles.

Permit the necessary groups or user IDs access to these profiles, so that they can use the ALTERNATE_USER_AUTHORITY options when the object is opened.

Profiles for alternate user security can be specified at subsystem level or at queue-sharing group level and take the following form:

```
hlq.ALTERNATE.USER.alternateuserid
```

Where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name), and `alternateuserid` is the value of the *AlternateUserId* field in the object descriptor.

A profile prefixed by the queue manager name controls use of an alternative user ID on that queue manager. A profile prefixed by the queue-sharing group name controls use of an alternative user ID on all queue managers within the queue-sharing group. This alternative user ID can be used on any queue manager within the queue-sharing group by a user that has the correct access. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that alternative user ID on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

The following table shows the access when specifying an alternative user option.

Table 56. Access levels for alternate user security

MQOPEN, MQSUB, or MQPUT1 option	RACF access level required
MQOO_ALTERNATE_USER_AUTHORITY MQSO_ALTERNATE_USER_AUTHORITY MQPMO_ALTERNATE_USER_AUTHORITY	UPDATE

In addition to alternate user security checks, other security checks for queue, process, namelist, and context security can also be made. The alternative user ID, if provided, is only used for security checks on queue, process definition, or namelist resources. For alternate user and context security checks, the user ID requesting that the check is used. For details about how user IDs are handled, see “User IDs for security checking” on page 617. For a summary table showing the open options and the security checks required when queue, context and alternate user security are all active, see Table 48 on page 589.

An alternative user profile gives the requesting user ID access to resources associated with the user ID specified in the alternative user ID. For example, the payroll server running under user ID PAYSERV on queue manager QMPY processes requests from personnel user IDs, all of which start with PS. To cause the work performed by the payroll server to be carried out under the user ID of the requesting user, alternative user authority is used. The payroll server knows which user ID to specify as the alternative user ID because the requesting programs generate messages using the MQPMO_DEFAULT_CONTEXT put message option. See “User IDs for security checking” on page 617 for more details about from where alternative user IDs are obtained.

The following example RACF definitions enable the server program to specify alternative user IDs starting with the characters PS:

```
RDEFINE MQADMIN QMPY.ALTERNATE.USER.PS* UACC(NONE)
PERMIT QMPY.ALTERNATE.USER.PS* CLASS(MQADMIN) ID(PAYSERV) ACCESS(UPDATE)
```

Note:

1. The `AlternateUserId` fields in the object descriptor and subscription descriptor are 12 bytes long. All 12 bytes are used in the profile checks, but only the first 8 bytes are used as the user ID by IBM MQ. If this user ID truncation is not desirable, application programs making the request must translate any alternative user ID over 8 bytes into something more appropriate.
2. If you specify MQOO_ALTERNATE_USER_AUTHORITY, MQSO_ALTERNATE_USER_AUTHORITY, or MQPMO_ALTERNATE_USER_AUTHORITY and you do not specify an `AlternateUserId` field in the object descriptor, a user ID of blanks is used. For the purposes of the alternate user security check the user ID used for the `AlternateUserId` qualifier is -BLANK-. For example `RDEF MQADMIN hlq.ALTERNATE.USER.-BLANK-`.

   If the user is allowed to access this profile, all further checks are made with a user ID of blanks. For details of blank user IDs, see “Blank user IDs and UACC levels” on page 625.

The administration of alternative user IDs is easier if you have a naming convention for user IDs that enables you to use generic alternative user profiles. If they do not, you can use the RACF RACVARS feature. For details about using RACVARS, see the *z/OS SecureWay Security Server RACF Security Administrator's Guide*.

When a message is put to a queue that has been opened with alternative user authority and the context of the message has been generated by the queue manager, the MQMD_USER_IDENTIFIER field is set to the alternative user ID.

Profiles for context security

IBM MQ uses profiles for controlling access to the context information specific to a particular message. The context is contained within the message descriptor (MQMD).

Using profiles for context security

If context security is active, you must:

- Define a profile in the **MQADMIN** class if using uppercase profiles.
- Define profile in the **MXADMIN** class if using mixed case profiles.

The profile is called `hlq.CONTEXT.queuename`, where:

hlq Can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name).

queuename
Can be either the full name of the queue you want to define the context profile for, or a generic profile.

A profile prefixed by the queue manager name, and with ** specified as the queue name, allows control for context security on all queues belonging to that queue manager. This can be overridden on an individual queue by defining a queue level profile for context on that queue.

A profile prefixed by the queue-sharing group name, and with ** specified as the queue name, allows control for context on all queues belonging to the queue managers within the queue-sharing group. This can be overridden on an individual queue manager by defining a queue-manager level profile for context on that queue manager, by specifying a profile prefixed by the queue manager name. It can also be overridden on an individual queue by specifying a profile suffixed with the queue name.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

You must give the necessary groups or user IDs access to this profile. The following table shows the access level required, depending on the specification of the context options when the queue is opened.

Table 57. Access levels for context security

MQOPEN or MQPUT1 option	RACF access level required to hlq.CONTEXT.queuename
MQPMO_NO_CONTEXT	No context security check
MQPMO_DEFAULT_CONTEXT	No context security check
MQOO_SAVE_ALL_CONTEXT	No context security check
MQOO_PASS_IDENTITY_CONTEXT MQPMO_PASS_IDENTITY_CONTEXT	READ
MQOO_PASS_ALL_CONTEXT MQPMO_PASS_ALL_CONTEXT	READ
MQOO_SET_IDENTITY_CONTEXT MQPMO_SET_IDENTITY_CONTEXT	UPDATE

Table 57. Access levels for context security (continued)

MQOPEN or MQPUT1 option	**RACF access level required to hlq.CONTEXT.queuename**
MQOO_SET_ALL_CONTEXT MQPMO_SET_ALL_CONTEXT	CONTROL
MQOO_OUTPUT or MQPUT1 (USAGE(XMITQ))	CONTROL
MQSUB option	
MQSO_SET_IDENTITY_CONTEXT **(Note 2)**	UPDATE

Note:

1. The user IDs used for distributed queuing require CONTROL access to `hlq.CONTEXT.queuename` to put messages on the destination queue. See "User IDs used by the channel initiator" on page 620 for information about the user IDs used.
2. If on the MQSUB request, with MQSO_CREATE or MQSO_ALTER options specified, you want to set any of the identity context fields in the MQSD structure, you need to specify the MQSO_SET_IDENTITY_CONTEXT option. You require also, the appropriate authority to the context profile for the destination queue.

If you put commands on the system-command input queue, use the default context put message option to associate the correct user ID with the command.

For example, the IBM MQ-supplied utility program CSQUTIL can be used to offload and reload messages in queues. When offloaded messages are restored to a queue, the CSQUTIL utility uses the MQOO_SET_ALL_CONTEXT option to return the messages to their original state. In addition to the queue security required by this open option, context authority is also required. For example, if this authority is required by the group BACKGRP on queue manager MQS1, this would be defined by:

```
RDEFINE MQADMIN MQS1.CONTEXT.** UACC(NONE)
PERMIT MQS1.CONTEXT.** CLASS(MQADMIN) ID(BACKGRP) ACCESS(CONTROL)
```

Depending on the options specified, and the types of security performed, other types of security checks might also occur when the queue is opened. These include queue security (see "Profiles for queue security" on page 581), and alternate user security (see "Profiles for alternate user security" on page 596). For a summary table showing the open options and the security checks required when queue, context and alternate user security are all active, see Table 48 on page 589.

System queue context security

Many of the system queues are accessed by the ancillary parts of IBM MQ, for example the channel initiator address space.

The user IDs under which this runs must be given RACF access to these queues, as shown in Table 58 on page 600.

Table 58. Access required to the SYSTEM queues for context operations

SYSTEM queue	Channel Initiator for Distributed queuing
SYSTEM.BROKER.CONTROL.QUEUE	CONTROL
SYSTEM.BROKER.INTER.BROKER.COMMUNICATIONS	CONTROL
SYSTEM.CHANNEL.SYNCQ	CONTROL
SYSTEM.CLUSTER.TRANSMIT.QUEUE	CONTROL

Profiles for command security

To enable security checking for commands, add profiles to the MQCMDS class. The profile names are based on the MQSC commands but control both MQSC and PCF commands. Profiles can apply to a queue manager or a queue-sharing group.

If you want security checking for commands (so you have not defined the command security switch profile hlq.NO.CMD.CHECKS) you must add profiles to the MQCMDS class.

The same security profiles control both MQSC and PCF commands. The names of the RACF profiles for command security checking are based on the MQSC command names themselves. These profiles take the form:

```
hlq.verb.pkw
```

Where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name), `verb` is the verb part of the command name, for example ALTER, and `pkw` is the object type, for example QLOCAL for a local queue.

Thus, the profile name for the ALTER QLOCAL command in subsystem CSQ1 is:

```
CSQ1.ALTER.QLOCAL
```

You can use generic profiles to protect sets of commands so that you have fewer profiles to maintain and, therefore, fewer access lists. Consider creating a generic profile that applies to all commands not protected by a more specific profile. Define this profile with UACC(NONE) and grant ALTER access only to the RACF groups containing administrators. You might then create a generic profile applicable to all DISPLAY commands and grant widespread access to it. Between these extremes, you might identify groups of users needing access to certain sets of commands, in which case you can create profiles for those sets and grant access to RACF groups representing those classes of user. Avoid giving users access to commands they do not require: Apply the principle of least privilege, so that users only have access to the commands that are required for their jobs.

A profile prefixed by the queue manager name controls the use of the command on that queue manager. A profile prefixed by the queue-sharing group name controls the use of the command on all queue managers within the queue-sharing group. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that command on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

By setting up command profiles at queue manager level, a user can be restricted from issuing commands on a particular queue manager. Alternatively, you can define one profile for a queue-sharing group for each command verb, and all security checks take place against that profile instead of individual queue managers.

If both subsystem security and queue-sharing group security are active and a local profile is not found, a command security check is performed to see if the user has access to a queue-sharing group profile.

If you use the CMDSCOPE attribute to route a command to other queue managers in a queue-sharing group, security is checked on each queue manager where the command is run, but not necessarily on the queue manager where the command is entered.

Table 59 shows, for each IBM MQ MQSC command, the profiles required for command security checking to be carried out, and the corresponding access level for each profile in the MQCMDS class.

Table 60 on page 605 shows, for each IBM MQ PCF command, the profiles required for command security checking to be carried out, and the corresponding access level for each profile in the MQCMDS class.

Notes:

1. These commands might be issued internally by the queue manager; no authority is checked in these cases.
2. IBM MQ does not check the authority of the user who issues the START QMGR command. However, you can use RACF, or your alternative security facilities to control access to the START xxxxMSTR command that is issued as a result of the START QMGR command. This is done by controlling access to the MVS.START.STC.xxxxMSTR profile in the RACF operator commands (OPERCMDS) class. For

details of this procedure, see the *z/OS SecureWay Security Server RACF Security Administrator's Guide*. If you use this technique, and an unauthorized user tries to start the queue manager, it terminates with a reason code of 00F30216.

3. The **`hlq.TOPIC.topic`** resource refers to the Topic object derived from the TOPICSTR. For more details, see "Publish/subscribe security" on page 821
4. At releases prior to IBM MQ for z/OS V6, the security check was for MVS.START.STC.CSQ1CHIN. At IBM MQ for z/OS V6 and later, the resource name has an additional JOBNAME qualifier appended to it. This can cause problems when starting the channel initiator.

   To resolve the problem replace MVS.START.STC. *ssid* CHIN with a profile for a resource named MVS.START.STC. *ssid* CHIN **.*** or MVS.START.STC. *ssid* CHIN. *ssid* CHIN where *ssid* is the subsystem id for the queue manager. This requires RACF UPDATE authority. For more details, see the z/OS product documentation for *Operation planning, MVS Commands, RACF Access Authorities, and Resource Names*.

   The START for *ssid* MSTR does not include the JOBNAME= parameter. For consistency, you might want to update the profile for MVS.START.STC.ssidMSTR to MVS.START.STC.ssidMSTR.*.

Profiles for command resource security

If you have not defined the command resource security switch profile, because you want security checking for resources associated with commands, you must add resource profiles for each resource to the appropriate class. The same security profiles control both MQSC and PCF commands.

If you have not defined the command resource security switch profile, `hlq.NO.CMD.RESC.CHECKS`, because you want security checking for resources associated with commands, you must:

- Add a resource profile in the **MQADMIN** class, if using uppercase profiles, for each resource.
- Add a resource profile in the **MXADMIN** class, if using mixed case profiles, for each resource.

The same security profiles control both MQSC and PCF commands.

Profiles for command resource security checking take the form:

```
hlq.type.resourcename
```

where `hlq` can be either `qmgr-name` (queue manager name) or `qsg-name` (queue-sharing group name).

A profile prefixed by the queue manager name controls access to the resources associated with commands on that queue manager. A profile prefixed by the queue-sharing group name controls access to the resources associated with commands on all queue managers within the queue-sharing group. This access can be overridden on an individual queue manager by defining a queue-manager level profile for that command resource on that queue manager.

If your queue manager is a member of a queue-sharing group and you are using both queue manager and queue-sharing group level security, IBM MQ checks for a profile prefixed by the queue manager name first. If it does not find one, it looks for a profile prefixed by the queue-sharing group name.

For example, the RACF profile name for command resource security checking against the model queue CREDIT.WORTHY in subsystem CSQ1 is:

```
CSQ1.QUEUE.CREDIT.WORTHY
```

Because the profiles for all types of command resource are held in the MQADMIN class, the "type" part of the profile name is needed in the profile to distinguish between resources of different types that have the same name. The "type" part of the profile name can be CHANNEL, QUEUE, TOPIC, PROCESS, or NAMELIST. For example, a user might be authorized to define hlq.QUEUE.PAYROLL.ONE, but not authorized to define hlq.PROCESS.PAYROLL.ONE

If the resource type is a queue, and the profile is a queue-sharing group level profile, it controls access to one or more local queues within the queue sharing group, or access to a single shared queue from any queue manager in the queue-sharing group.

z/OS MQSC commands, profiles, and their access levels shows, for each IBM MQ MQSC command, the profiles required for command security checking to be carried out, and the corresponding access level for each profile in the MQCMDS class.

z/OS PCF commands, profiles, and their access levels shows, for each IBM MQ PCF command, the profiles required for command security checking to be carried out, and the corresponding access level for each profile in the MQCMDS class.

Command resource security checking for alias queues and remote queues:

Alias queue and remote queues both provide indirection to another queue. Additional points apply when you consider security checking for these queues.

Alias queues

When you define an alias queue, command resource security checks are only performed against the name of the alias queue, not against the name of the target queue to which the alias resolves.

Alias queues can resolve to both local and remote queues. If you do not want to permit users access to certain local or remote queues, you must do both of the following:
1. Do not allow the users access to these local and remote queues.
2. Restrict the users from being able to define aliases for these queues. That is, prevent them from being able to issue DEFINE QALIAS and ALTER QALIAS commands.

Remote queues

When you define a remote queue, command resource security checks are performed only against the name of the remote queue. No checks are performed against the names of the queues specified in the RNAME or XMITQ attributes in the remote queue object definition.

The RESLEVEL security profile

You can define a special profile in the MQADMIN or MXADMIN class to control the number of user IDs checked for API-resource security. This profile is called the RESLEVEL profile. How this profile affects API-resource security depends on how you access IBM MQ.

When an application tries to connect to IBM MQ, IBM MQ checks the access that the user ID associated with the connection has to a profile in the MQADMIN or MXADMIN class called:

```
hlq.RESLEVEL
```

Where `hlq` can be either `ssid` (subsystem ID) or `qsg` (queue-sharing group ID).

The user IDs associated with each connection type are:
- The user ID of the connecting task for batch connections
- The CICS address space user ID for CICS connections
- The IMS region address space user ID for IMS connections
- The channel initiator address space user ID for channel initiator connections

Attention: RESLEVEL is a very powerful option; it can cause the bypassing of all resource security checks for a particular connection.

If you do not have a RESLEVEL profile defined, you must be careful that no other profile in the MQADMIN class matches hlq.RESLEVEL. For example, if you have a profile in MQADMIN called hlq.** and no hlq.RESLEVEL profile, beware of the consequences of the hlq.** profile because it is used for the RESLEVEL check.

Define an hlq.RESLEVEL profile and set the UACC to NONE, rather than have no RESLEVEL profile at all. Have as few users or groups in the access list as possible. For details about how to audit RESLEVEL access, see "Auditing considerations on z/OS" on page 637.

If you are using queue manager level security only, IBM MQ performs RESLEVEL checks against the `qmgr-name.RESLEVEL` profile. If you are using queue-sharing group level security only, IBM MQ performs RESLEVEL checks against the `qsg-name.RESLEVEL` profile. If you are using a combination of both queue manager and queue-sharing group level security, IBM MQ first checks for the existence of a RESLEVEL profile at queue manager level. If it does not find one, it checks for a RESLEVEL profile at queue-sharing group level.

If it cannot find a RESLEVEL profile, IBM MQ enables checking of both the job and task (or alternate user) ID for a CICS or an IMS connection. For a batch connection, IBM MQ enables checking of the job (or alternate) user ID. For the channel initiator, IBM MQ enables checking of the channel user ID and the MCA (or alternate) user ID.

If there is a RESLEVEL profile, the level of checking depends on the environment and access level for the profile.

Remember that if your queue manager is a member of a queue-sharing group and you do not define this profile at queue-manager level, there might be one defined at queue-sharing group level that will affect the level of checking.To activate the checking of two user IDs, you define a RESLEVEL profile (prefixed with either the queue manager name of the queue-sharing group name) with a UACC(NONE) and ensure that the relevant users do not have access granted against this profile.

When you consider the access that the channel initiator's user ID has to RESLEVEL, remember that the connection established by the channel initiator is also the connection used by the channels. A setting that causes the bypassing of all resource security checks for the channel initiator's user ID effectively bypasses security checks for all channels. If the channel initiator's user ID access to RESLEVEL is something other than NONE, then only one user ID (for an access level of READ or UPDATE) or no user IDs (for an access level of CONTROL or ALTER) is checked for access. If you grant the channel initiator's user ID an access level other than NONE to RESLEVEL, be sure that you understand the effect of this setting on the security checks done for channels.

Using the RESLEVEL profile means that normal security audit records are not taken. For example, if you put UAUDIT on a user, the access to the hlq.RESLEVEL profile in MQADMIN is not audited.

If you use the RACF WARNING option on the hlq.RESLEVEL profile, no RACF warning messages are produced for profiles in the RESLEVEL class.

Security checking for report messages such as CODs are controlled by the RESLEVEL profile associated with the originating application. For example, if a batch job's userid has CONTROL or ALTER authority to a RESLEVEL profile, then all resource checking performed by the batch job are bypassed, including the security check of report messages.

If you change the RESLEVEL profile, users must disconnect and connect again before the change takes place. (This includes stopping and restarting the channel initiator if the access that the distributed queuing address space user ID has to the RESLEVEL profile is changed.)

To switch RESLEVEL auditing off, use the RESAUDIT system parameter.

RESLEVEL and batch connections

By default, when an IBM MQ resource is being accessed through batch and batch-type connections, the user must be authorized to access that resource for the particular operation. You can bypass the security check by setting up an appropriate RESLEVEL definition.

Whether the user is checked or not is based on the user ID used at connect time, the same user ID used for the connection check.

For example, you can set up RESLEVEL so that when a user you trust accesses certain resources through a batch connection, no API-resource security checks are done; but when a user you do not trust tries to access the same resources, security checks are carried out as normal. You should set up RESLEVEL checking to bypass API-resource security checks only when you sufficiently trust the user and the programs run by that user.

The following table shows the checks made for batch connections.

Table 61. Checks made at different RACF access levels for batch connections

RACF access level	Level of checking
NONE	Resource checks performed
READ	Resource checks performed
UPDATE	Resource checks performed
CONTROL	No check.
ALTER	No check.

RESLEVEL and system functions

The application of RESLEVEL to the operation and control panels, and to CSQUTIL.

The operation and control panels and the CSQUTIL utility are batch-type applications that make requests to the queue manager's command server, and so they are subject to the considerations described in “RESLEVEL and batch connections.” You can use RESLEVEL to bypass security checking for the SYSTEM.COMMAND.INPUT and SYSTEM.COMMAND.REPLY.MODEL queues that they use, but not for the dynamic queues SYSTEM.CSQXCMD.*, SYSTEM.CSQOREXX.*, and SYSTEM.CSQUTIL.*.

The command server is an integral part of the queue manager and so does not have connection or RESLEVEL checking associated with it. To maintain security, therefore, the command server must confirm that the user ID of the requesting application has authority to open the queue being used for replies. For the operations and control panels, this is SYSTEM.CSQOREXX.*. For CSQUTIL, it is SYSTEM.CSQUTIL.*. Users must be authorized to use these queues, as described in “System queue security” on page 588, in addition to any RESLEVEL authorization they are given.

For other applications using the command server, it is the queue they name as their reply-to queue. Such other applications might deceive the command server into placing messages on unauthorized queues by passing (in the message context) a more trusted user ID than its own to the command server. To prevent this, use a CONTEXT profile to protect the identity context of messages placed on SYSTEM.COMMAND.INPUT.

RESLEVEL and CICS connections

By default, when an API-resource security check is made on a CICS connection, two user IDs are checked. You can change which user IDs are checked by setting up a RESLEVEL profile.

The first user ID checked is that of the CICS address space. This is the user ID on the job card of the CICS job, or the user ID assigned to the CICS started task by the z/OS STARTED class or the started procedures table. (It is not the CICS DFLTUSER.)

The second user ID checked is the user ID associated with the CICS transaction.

If one of these user IDs does not have access to the resource, the request fails with a completion code of MQRC_NOT_AUTHORIZED. Both the CICS address space user ID and the user ID of the person running the CICS transaction must have access to the resource at the correct level.

How RESLEVEL can affect the checks made

Depending on how you set up your RESLEVEL profile, you can change which user IDs are checked when access to a resource is requested. See Table 62 for more information.

The user IDs checked depend on the user ID used at connection time, that is, the CICS address space user ID. This control enables you to bypass API-resource security checking for IBM MQ requests coming from one system (for example, a test system, TESTCICS,) but to implement them for another (for example, a production system, PRODCICS).

Note: If you set up your CICS address space user ID with the “trusted” attribute in the STARTED class or the RACF started procedures table ICHRIN03, this overrides any user ID checks for the CICS address space established by the RESLEVEL profile for your queue manager (that is, the queue manager does not perform the security checks for the CICS address space). For more information, see the *CICS Transaction Server for z/OS V3.2 RACF Security Guide*.

The following table shows the checks made for CICS connections.

Table 62. Checks made at different RACF access levels for CICS connections

RACF access level	Level of checking
NONE	IBM MQ checks the CICS address space user ID and the transaction user ID.
READ	IBM MQ checks the CICS address space user ID only.
UPDATE	If the transaction is defined to CICS with RESSEC(YES), IBM MQ checks the CICS address space user ID and the transaction user ID.
UPDATE	If the transaction is defined to CICS with RESSEC(NO), IBM MQ checks the CICS address space user ID only.
CONTROL or ALTER	IBM MQ does not check any user IDs.

RESLEVEL and IMS connections

By default, when an API-resource security check is made for an IMS connection, two user IDs are checked. You can change which user IDs are checked by setting up a RESLEVEL profile.

By default, when an API-resource security check is made for an IMS connection, two user IDs are checked to see if access is allowed to the resource.

The first user ID checked is that of the address space of the IMS region. This is taken from either the USER field from the job card or the user ID assigned to the region from the z/OS STARTED class or the started procedures table (SPT).

The second user ID checked is associated with the work being done in the dependent region. It is determined according to the type of the dependent region as shown in How the second user ID is determined for the IMS(tm) connection.

If either the first or second IMS user ID does not have access to the resource, the request fails with a completion code of MQRC_NOT_AUTHORIZED.

The setting of IBM MQ RESLEVEL profiles cannot alter the user ID under which IMS transactions are scheduled from the IBM-supplied MQ-IMS trigger monitor program CSQQTRMN. This user ID is the PSBNAME of that trigger monitor, which by default is CSQQTRMN.

How RESLEVEL can affect the checks made

Depending on how you set up your RESLEVEL profile, you can change which user IDs are checked when access to a resource is requested. The possible checks are:

- Check the IMS region address space user ID and the second user ID or alternate user ID.
- Check IMS region address space user ID only.
- Do not check any user IDs.

The following table shows the checks made for IMS connections.

Table 63. Checks made at different RACF access levels for IMS connections

RACF access level	Level of checking
NONE	Check the IMS address space user ID and the IMS second user ID or alternate user ID.
READ	Check the IMS address space user ID.
UPDATE	Check the IMS address space user ID.
CONTROL	No check.
ALTER	No check.

RESLEVEL and the channel initiator connection

By default, when an API-resource security check is made by the channel initiator, two user IDs are checked. You can change which user IDs are checked by setting up a RESLEVEL profile.

By default, when an API-resource security check is made by the channel initiator, two user IDs are checked to see if access is allowed to the resource.

The user IDs checked can be that specified by the MCAUSER channel attribute, that received from the network, that of the channel initiator address space, or the alternate user ID for the message descriptor. Which user IDs are checked depends on the communication protocol you are using and the setting of the PUTAUT channel attribute. See "User IDs used by the channel initiator" on page 620 for more information.

If one of these user IDs does not have access to the resource, the request fails with a completion code of MQRC_NOT_AUTHORIZED.

How RESLEVEL can affect the checks made

Depending on how you set up your RESLEVEL profile, you can change which user IDs are checked when access to a resource is requested, and how many are checked.

The following table shows the checks made for the channel initiator's connection, and for all channels since they use this connection.

Table 64. Checks made at different RACF access levels for channel initiator connections

RACF access level	Level of checking
NONE	Check two user IDs.
READ	Check one user ID.
UPDATE	Check one user ID.
CONTROL	No check.
ALTER	No check.
Note: See "User IDs used by the channel initiator" on page 620 for a definition of the user IDs checked	

RESLEVEL and intra-group queuing

By default, when an API-resource security check is made by the intra-group queuing agent, two user IDs are checked to see if access is allowed to the resource. You can change which user IDs are checked by setting up an RESLEVEL profile.

The user IDs checked can be the user ID determined by the IGQUSER attribute of the receiving queue manager, the user ID of the queue manager within the queue-sharing group that put the message on to the SYSTEM.QSG.TRANSMIT.QUEUE, or the alternate user ID specified in the `UserIdentifier` field of the message descriptor of the message. See "User IDs used by the intra-group queuing agent" on page 624 for more information.

Because the intra-group queuing agent is an internal queue manager task, it does not issue an explicit connect request and runs under the user ID of the queue manager. The intra-group queuing agent starts at queue manager initialization. During the initialization of the intra-group queuing agent, IBM MQ checks the access that the user ID associated with the queue manager has to a profile in the MQADMIN class called:

```
hlq.RESLEVEL
```

This check is always performed unless the hlq.NO.SUBSYS.SECURITY switch has been set.

If there is no RESLEVEL profile, IBM MQ enables checking for two user IDs. If there is a RESLEVEL profile, the level of checking depends on the access level granted to the user ID of the queue manager for the profile. Checks made at different RACF(r) access levels for the intra-group queuing agent shows the checks made for the intra-group queuing agent.

Table 65. Checks made at different RACF access levels for the intra-group queuing agent

RACF access level	Level of checking
NONE	Check two user IDs.
READ	Check one user ID.
UPDATE	Check one user ID.
CONTROL	No check.
ALTER	No check.
Note: See “User IDs used by the intra-group queuing agent” on page 624 for a definition of the user IDs checked	

If the permissions granted to the RESLEVEL profile for the queue manager's user ID are changed, the intra-group queuing agent must be stopped and restarted to pick up the new permissions. Because there is no way to independently stop and restart the intra-group queuing agent, the queue manager must be stopped and restarted to achieve this.

RESLEVEL and the user IDs checked

Example of setting a RESLEVEL profile and granting access to it.

User ID checking against profile name for batch connections through User IDs checked against profile name for LU 6.2 and TCP/IP server-connection channels show how RESLEVEL affects which user IDs are checked for different MQI requests.

For example, you have a queue manager called QM66 with the following requirements:

- User WS21B is to be exempt from resource security.
- CICS started task WXNCICS running under address space user ID CICSWXN is to perform full resource checking only for transactions defined with RESSEC(YES).

To define the appropriate RESLEVEL profile, issue the following RACF command:

```
RDEFINE MQADMIN QM66.RESLEVEL UACC(NONE)
```

Then give the users access to this profile, using the following commands:

```
PERMIT QM66.RESLEVEL CLASS(MQADMIN) ID(WS21B) ACCESS(CONTROL)
PERMIT QM66.RESLEVEL CLASS(MQADMIN) ID(CICSWXN) ACCESS(UPDATE)
```

If you make these changes while the user IDs are connected to queue manager QM66, the users must disconnect and connect again before the change takes place.

If subsystem security is not active when a user connects but, while this user is still connected, subsystem security becomes active, full resource security checking is applied to the user. The user must reconnect to get the correct RESLEVEL processing.

User IDs for security checking

IBM MQ initiates security checks based on user IDs associated with users, terminals, applications, and other resources. This collection of topics lists which user IDs are used for each type of security check.

User IDs for connection security

The user ID used for connection security depends on the type of connection.

Connection type	User ID contents
Batch connection	The user ID of the connecting task. For example: • The TSO user ID • The user ID assigned to a batch job by the USER JCL parameter • The user ID assigned to a started task by the STARTED class or the started procedures table
CICS connection	The CICS address space user ID.
IMS connection	The IMS region address space user ID.
Channel initiator connection	The channel initiator address space user ID.

User IDs for command security and command resource security

The user ID used for command security or command resource security depends on where the command is issued from.

Issued from...	User ID contents
CSQINP1, CSQINP2, or CSQINPT	No check is made.
System command input queue	The user ID found in the `UserIdentifier` of the message descriptor of the message that contains the command. If the message does not contain a `UserIdentifier`, a user ID of blanks is passed to the security manager.
Console	The user ID signed onto the console. If the console is not signed on, the default user ID set by the CMDUSER system parameter in CSQ6SYSP. To issue commands from a console, the console must have the z/OS SYS AUTHORITY attribute.
SDSF/TSO console	TSO or job user ID.
Operations and control panels	TSO user ID. If you are going to use the operations and control panels, you must have the appropriate authority to issue the commands corresponding to the actions that you choose. In addition, you must have READ access to all the hlq.DISPLAY. *object* profiles in the MQCMDS class because the panels use the various DISPLAY commands to gather the information that they present.
MGCRE	If MGCRE is used with UTOKEN, the user ID in the UTOKEN. If MGCRE is issued without the UTOKEN, the TSO or job user ID is used.
CSQ0UTIL	Job user ID.
CSQUTIL	Job user ID.
CSQINPX	User ID of the channel initiator address space.

User IDs for resource security (MQOPEN, MQSUB, and MQPUT1)

This information shows the contents of the user IDs for normal and alternate user IDs for each type of connection. The number of checks is defined by the RESLEVEL profile. The user ID checked is that used for **MQOPEN**, **MQSUB**, or **MQPUT1** calls.

Note: All user ID fields are checked exactly as they are received. No conversions take place, and, for example, three user ID fields containing “Bob”, “BOB”, and “bob” are not equivalent.

User IDs checked for batch connections:

The user ID checked for a batch connection depends on how the task is run and whether an alternate user ID has been specified.

Table 66. User ID checking against profile name for batch connections

Alternate user ID specified on open?	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
No	-	JOB	JOB
Yes	JOB	JOB	ALT

Key:

ALT Alternate user ID.

JOB

- The user ID of a TSO or USS sign-on.
- The user ID assigned to a batch job.
- The user ID assigned to a started task by the STARTED class or the started procedures table.
- The user ID associated with the executing Db2 stored procedure

A Batch job is performing an **MQPUT1** to a queue called Q1 with RESLEVEL set to READ and alternate user ID checking turned off.

Checks made at different RACF(r) access levels for batch connections and User ID checking against profile name for batch connections show that the job user ID is checked against profile hlq.Q1.

User IDs checked for CICS connections:

The user IDs checked for CICS connections depend on whether one or two checks are to be carried out, and whether an alternate user ID is specified.

Table 67. User ID checking against profile name for CICS-type user IDs

Alternate user ID specified on open?	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
No, 1 check	-	ADS	ADS
No, 2 checks	-	ADS+TXN	ADS+TXN
Yes, 1 check	ADS	ADS	ADS
Yes, 2 checks	ADS+TXN	ADS+TXN	ADS+ALT

Key:

ALT Alternate user ID

ADS The user ID associated with the CICS batch job or, if CICS is running as a started task, through the STARTED class or the started procedures table.

TXN The user ID associated with the CICS transaction. This is normally the user ID of the terminal user who started the transaction. It can be the CICS DFLTUSER, a PRESET security terminal, or a manually signed-on user.

Determine the user IDs checked for the following conditions:
- The RACF access level to the RESLEVEL profile, for a CICS address space user ID, is set to NONE.
- An **MQOPEN** call is made against a queue with MQOO_OUTPUT and MQOO_PASS_IDENTITY_CONTEXT.

First, see how many CICS user IDs are checked based on the CICS address space user ID access to the RESLEVEL profile. From Table 62 on page 613 in topic "RESLEVEL and CICS connections" on page 613, two user IDs are checked if the RESLEVEL profile is set to NONE. Then, from Table 67 on page 618 on, these checks are carried out:
- The hlq.ALTERNATE.USER.userid profile is not checked.
- The hlq.CONTEXT.queuename profile is checked with both the CICS address space user ID and the CICS transaction user ID.
- The hlq.resourcename profile is checked with both the CICS address space user ID and the CICS transaction user ID.

This means that four security checks are made for this **MQOPEN** call.

User IDs checked for IMS connections:

The user IDs checked for IMS connections depend on whether one or two checks are to be performed, and whether an alternate user ID is specified. If a second user ID is checked, it depends on the type of dependent region and on which user IDs are available.

Table 68. User ID checking against profile name for IMS-type user IDs

Alternate user ID specified on open?	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
No, 1 check	-	REG	REG
No, 2 checks	-	REG+SEC	REG+SEC
Yes, 1 check	REG	REG	REG
Yes, 2 checks	REG+SEC	REG+SEC	REG+ALT

Key:

ALT Alternate user ID.

REG The user ID is normally set through the STARTED class or the started procedures table or, if IMS is running, from a submitted job, by the USER JCL parameter.

SEC The second user ID is associated with the work being done in a dependent region. It is determined according to Table 69 on page 620.

Table 69. How the second user ID is determined for the IMS connection

Types of dependent region	Hierarchy for determining the second user ID
• BMP message driven and successful GET UNIQUE issued. • IFP and GET UNIQUE issued. • MPP.	User ID associated with the IMS transaction if the user is signed on. LTERM name if available. PSBNAME.
• BMP message driven and successful GET UNIQUE not issued. • BMP not message driven. • IFP and GET UNIQUE not issued.	User ID associated with the IMS dependent region address space if this is not all blanks or all zeros. PSBNAME.

User IDs used by the channel initiator:

This collection of topics describes the user IDs used and checked for receiving channels and for client MQI requests issued over server-connection channels. Information is provided for TCP/IP and for LU6.2

You can use the PUTAUT parameter of the receiving channel definition to determine the type of security checking used. To get consistent security checking throughout your IBM MQ network, you can use the ONLYMCA and ALTMCA options.

You can use the DISPLAY CHSTATUS command to determine the user identifier used by the MCA.

Receiving channels using TCP/IP:

The user IDs checked depend on the PUTAUT option of the channel and on whether one or two checks are to be performed.

Table 70. User IDs checked against profile name for TCP/IP channels

PUTAUT option specified on receiver or requester channel	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
DEF, 1 check	-	CHL	CHL
DEF, 2 checks	-	CHL + MCA	CHL + MCA
CTX, 1 check	CHL	CHL	CHL
CTX, 2 checks	CHL + MCA	CHL + MCA	CHL + ALT
ONLYMCA, 1 check	-	MCA	MCA
ONLYMCA, 2 checks	-	MCA	MCA
ALTMCA, 1 check	MCA	MCA	MCA
ALTMCA, 2 checks	MCA	MCA	MCA + ALT

Key:

MCA (MCA user ID)
The user ID specified for the MCAUSER channel attribute at the receiver; if blank, the channel initiator address space user ID of the receiver or requester side is used.

CHL (Channel user ID)
On TCP/IP, security is not supported by the communication system for the channel. If the Secure Sockets Layer (SSL) is being used and a digital certificate has been flowed from the partner, the user ID associated with this certificate (if installed), or the user ID associated with a matching

filter found by using RACF Certificate Name Filtering (CNF), is used. If no associated user ID is found, or if SSL is not being used, the user ID of the channel initiator address space of the receiver or requester end is used as the channel user ID on channels defined with the PUTAUT parameter set to DEF or CTX.

Note: The use of RACF Certificate Name Filtering (CNF) allows you to assign the same RACF user ID to multiple remote users, for example all the users in the same organization unit, who would naturally all have the same security authority. This means that the server does not have to have a copy of the certificate of every possible remote end user across the world and greatly simplifies certificate management and distribution.

If the PUTAUT parameter is set to ONLYMCA or ALTMCA for the channel, the channel user ID is ignored and the MCA user ID of the receiver or requester is used. This also applies to TCP/IP channels using SSL.

ALT (Alternate user ID)
The user ID from the context information (that is, the `UserIdentifier` field) within the message descriptor of the message. This user ID is moved into the `AlternateUserID` field in the object descriptor before an **MQOPEN** or **MQPUT1** call is issued for the target destination queue.

Receiving channels using LU 6.2:

The user IDs checked depend on the PUTAUT option of the channel and on whether one or two checks are to be performed.

Table 71. User IDs checked against profile name for LU 6.2 channels

PUTAUT option specified on receiver or requester channel	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
DEF, 1 check	-	CHL	CHL
DEF, 2 checks	-	CHL + MCA	CHL + MCA
CTX, 1 check	CHL	CHL	CHL
CTX, 2 checks	CHL + MCA	CHL + MCA	CHL + ALT
ONLYMCA, 1 check	-	MCA	MCA
ONLYMCA, 2 checks	-	MCA	MCA
ALTMCA, 1 check	MCA	MCA	MCA
ALTMCA, 2 checks	MCA	MCA	MCA + ALT

Key:

MCA (MCA user ID)
The user ID specified for the MCAUSER channel attribute at the receiver; if blank, the channel initiator address space user ID of the receiver or requester side is used.

CHL (Channel user ID)

Requester-server channels
If the channel is started from the requester, there is no opportunity to receive a network user ID (the channel user ID).

If the PUTAUT parameter is set to DEF or CTX on the requester channel, the channel user ID is that of the channel initiator address space of the requester because no user ID is received from the network.

If the PUTAUT parameter is set to ONLYMCA or ALTMCA, the channel user ID is ignored and the MCA user ID of the requester is used.

Other channel types

If the PUTAUT parameter is set to DEF or CTX on the receiver or requester channel, the channel user ID is the user ID received from the communications system when the channel is initiated.

- If the sending channel is on z/OS, the channel user ID received is the channel initiator address space user ID of the sender.
- If the sending channel is on a different platform (for example, AIX or HP-UX), the channel user ID received is typically provided by the USERID parameter of the channel definition.

If the user ID received is blank, or no user ID is received, a channel user ID of blanks is used.

ALT (Alternate user ID)

The user ID from the context information (that is, the `UserIdentifier` field) within the message descriptor of the message. This user ID is moved into the `AlternateUserID` field in the object descriptor before an **MQOPEN** or **MQPUT1** call is issued for the target destination queue.

Client MQI requests:

Various user IDs can be used, depending on which user IDs and environment variables have been set. These user IDs are checked against various profiles, depending on the PUTAUT option used and whether an alternate user ID is specified.

This section describes the user IDs checked for client MQI requests issued over server-connection channels for TCP/IP and LU 6.2. The MCA user ID and channel user ID are as for the TCP/IP and LU 6.2 channels described in the previous sections.

For server-connection channels, the user ID received from the client is used if the MCAUSER attribute is blank.

See "Access control for clients" on page 467 for more information.

For client **`MQOPEN`**, **`MQSUB`**, and **`MQPUT1`** requests, use the following rules to determine the profile that is checked:

- If the request specifies alternate-user authority, a check is made against the *hlq*.ALTERNATE.USER. *userid* profile.
- If the request specifies context authority, a check is made against the *hlq*.CONTEXT. *queuename* profile.
- For all **`MQOPEN`**, **`MQSUB`**, and **`MQPUT1`** requests, a check is made against the *hlq.resourcename* profile.

When you have determined which profiles are checked, use the following table to determine which user IDs are checked against these profiles.

Table 72. User IDs checked against profile name for LU 6.2 and TCP/IP server-connection channels

PUTAUT option specified on server-connection channel	Alternate user ID specified on open?	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
DEF, 1 check	No	-	CHL	CHL
DEF, 1 check	Yes	CHL	CHL	CHL
DEF, 2 checks	No	-	CHL + MCA	CHL + MCA

Table 72. User IDs checked against profile name for LU 6.2 and TCP/IP server-connection channels (continued)

PUTAUT option specified on server-connection channel	Alternate user ID specified on open?	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
DEF, 2 checks	Yes	CHL + MCA	CHL + MCA	CHL + ALT
ONLYMCA, 1 check	No	-	MCA	MCA
ONLYMCA, 1 check	Yes	MCA	MCA	MCA
ONLYMCA, 2 checks	No	-	MCA	MCA
ONLYMCA, 2 checks	Yes	MCA	MCA	MCA + ALT

Key:

MCA (MCA user ID)
The user ID specified for the MCAUSER channel attribute at the server-connection; if blank, the channel initiator address space user ID is used.

CHL (Channel user ID)
On TCP/IP, security is not supported by the communication system for the channel. If the Secure Sockets Layer (SSL) is being used and a digital certificate has been flowed from the partner, the user ID associated with this certificate (if installed), or the user ID associated with a matching filter found by using RACF Certificate Name Filtering (CNF), is used. If no associated user ID is found, or if SSL is not being used, the user ID of the channel initiator address space is used as the channel user ID on channels defined with the PUTAUT parameter set to DEF or CTX.

Note: The use of RACF Certificate Name Filtering (CNF) allows you to assign the same RACF user ID to multiple remote users, for example all the users in the same organization unit, who would naturally all have the same security authority. This means that the server does not have to have a copy of the certificate of every possible remote end user across the world and greatly simplifies certificate management and distribution.

If the PUTAUT parameter is set to ONLYMCA or ALTMCA for the channel, the channel user ID is ignored and the MCA user ID of the server-connection channel is used. This also applies to TCP/IP channels using SSL.

ALT (Alternate user ID)
The user ID from the context information (that is, the `UserIdentifier` field) within the message descriptor of the message. This user ID is moved into the `AlternateUserID` field in the object or subscription descriptor before an **MQOPEN**, **MQSUB** or **MQPUT1** call is issued on behalf of the client application.

Channel initiator example:

An example of how user IDs are checked against RACF profiles.

A user performs an **MQPUT1** operation to a queue on queue manager QM01 that resolves to a queue called QB on queue manager QM02. The message is sent on a TCP/IP channel called QM01.TO.QM02. RESLEVEL is set to NONE, and the open is performed with alternate user ID and context checking. The receiver channel definition has PUTAUT(CTX) and the MCA user ID is set. Which user IDs are used on the receiving channel to put the message to queue QB?

Answer: Table 64 on page 615 shows that two user IDs are checked because RESLEVEL is set to NONE.

Table 70 on page 620 shows that, with PUTAUT set to CTX and 2 checks, the following user IDs are checked:
- The channel initiator user ID and the MCAUSER user ID are checked against the hlq.ALTERNATE.USER.userid profile.
- The channel initiator user ID and the MCAUSER user ID are checked against the hlq.CONTEXT.queuename profile.
- The channel initiator user ID and the alternate user ID specified in the message descriptor (MQMD) are checked against the hlq.Q2 profile.

User IDs used by the intra-group queuing agent:

The user IDs that are checked when the intra-group queuing agent opens destination queues are determined by the values of the IGQAUT and IGQUSER queue manager attributes.

The possible user IDs are:

Intra-group queuing user ID (IGQ)

The user ID determined by the IGQUSER attribute of the receiving queue manager. If this is set to blanks, the user ID of the receiving queue manager is used. However, because the receiving queue manager has authority to access all queues defined to it, security checks are not performed for the receiving queue manager's user ID. In this case:
- If only one user ID is to be checked and the user ID is that of the receiving queue manager, no security checks take place. This can occur when IGAUT is set to ONLYIGQ or ALTIGQ.
- If two user IDs are to be checked and one of the user IDs is that of the receiving queue manager, security checks take place for the other user ID only. This can occur when IGAUT is set to DEF, CTX, or ALTIGQ.
- If two user IDs are to be checked and both user IDs are that of the receiving queue manager, no security checks take place. This can occur when IGAUT is set to ONLYIGQ.

Sending queue manager user ID (SND)

The user ID of the queue manager within the queue-sharing group that put the message on to the SYSTEM.QSG.TRANSMIT.QUEUE.

Alternate user ID (ALT)

The user ID specified in the *UserIdentifier* field in the message descriptor of the message.

Table 73. User IDs checked against profile name for intra-group queuing

IGQAUT option specified on receiving queue manager	hlq.ALTERNATE.USER.userid profile	hlq.CONTEXT.queuename profile	hlq.resourcename profile
DEF, 1 check	-	SND	SND
DEF, 2 checks	-	SND +IGQ	SND +IGQ
CTX, 1 check	SND	SND	SND
CTX, 2 checks	SND + IGQ	SND +IGQ	SND + ALT
ONLYIGQ, 1 check	-	IGQ	IGQ
ONLYIGQ, 2 checks	-	IGQ	IGQ
ALTIGQ, 1 check	-	IGQ	IGQ
ALTIGQ, 2 checks	IGQ	IGQ	IGQ + ALT

Key:

ALT	Alternate user ID.
IGQ	IGQ user ID.
SND	Sending queue manager user ID.

Blank user IDs and UACC levels

If a blank user ID occurs, a RACF undefined user is signed on. Do not grant wide-ranging access to the undefined user.

Blank user IDs can exist when a user is manipulating messages using context or alternate-user security, or when IBM MQ is passed a blank user ID. For example, a blank user ID is used when a message is written to the system-command input queue without context.

Note: A user ID of " * " (that is, an asterisk character followed by seven spaces) is treated as an undefined user ID.

IBM MQ passes the blank user ID to RACF and a RACF undefined user is signed on. All security checks then use the universal access (UACC) for the relevant profile. Depending on how you have set your access levels, the UACC might give the undefined user a wide-ranging access.

For example, if you issue this RACF command from TSO:

```
RDEFINE MQQUEUE Q.AVAILABLE.TO.EVERYONE UACC(UPDATE)
```

you define a profile that enables both z/OS-defined user IDs (that have not been put in the access list) and the RACF undefined user ID to put messages on, and get messages from, that queue.

To protect against blank user IDs you must plan your access levels carefully, and limit the number of people who can use context and alternate-user security. You must prevent people using the RACF undefined user ID from getting access to resources that they must not access. However, at the same time, you must allow access to people with defined user IDs. To do this, you can specify a user ID of asterisk (*) in a RACF command PERMIT, giving access to resources for all defined user IDs. Therefore all undefined user IDs (such as " * ") are denied access. For example, these RACF commands prevent the RACF undefined user ID from gaining access to the queue to put or get messages:

```
RDEFINE MQQUEUE Q.AVAILABLE.TO.RACF.DEFINED.USERS.ONLY UACC(NONE)
PERMIT Q.AVAILABLE.TO.RACF.DEFINED.USERS.ONLY CLASS(MQQUEUE) ACCESS(UPDATE) ID(*)
```

z/OS user IDs and Multi-Factor Authentication (MFA)

z/OS

IBM Multi-Factor Authentication for z/OS allows z/OS security administrators to enhance SAF authentication, by requiring identified users to use multiple authentication factors (for example, both a password and a cryptographic token) to sign on to a z/OS system. IBM MFA also provides support for time-based one time password generation technologies such as RSA SecureId.

For the most part, IBM MQ is unaware of how users have "logged on" to the CICS or batch systems that are driving IBM MQ work, the signed on user ID credential is associated with the z/OS task or address space and IBM MQ uses this for checking authorization to resources. User IDs enabled for MFA can be used for authorization to IBM MQ resources and authentication through pass tickets used with the CICS and IMS bridges.

Important: Special considerations apply however, when using applications, such as the MQ Explorer, which pass a user ID and password credentials on an MQCONNX API call with the *MQCSP_AUTH_USER_ID_AND_PWD* option. IBM MQ has no facility to pass an additional credential on this API request.

Limitations and potential workarounds are described in the following text.

MQ Explorer

The MQ Explorer cannot be used to log on to a z/OS system with a userid for which MFA is enabled because there is no facility for passing a second authentication factor from the MQ Explorer to z/OS.

Additionally, there are two different mechanisms used by the MQ Explorer to re-use a user ID and password credential, that need special attention when one time use passwords are in effect:

1. MQ Explorer has the capability to store passwords in an obfuscated format on the local machine for login at a later time. This capability must be disabled by having explorer prompt for a password each time a connection is made to the z/OS queue manager.

   To do this, use the following procedure:

   a. Select **Queue Managers**.
   b. From the list displayed, choose the queue manager you require and right click that queue manager.
   c. Select **Connection Details** from the menu list that appears.
   d. Select **Properties** from the next menu list and choose the **Userid** tab.

      Ensure that you select the **prompt for password** radio button.
2. Various operations in the MQ Explorer, such as browsing messages on queues, testing subscriptions, and so on, start a new thread which authenticates to IBM MQ using the credential first used at logon. Since the password credential cannot be re-used, you cannot use these operations.

There are two possible workarounds at the MFA configuration level for these issues:

- Use the application ID exclusion of MFA to exclude the IBM MQ tasks from MFA processing altogether.

  To do this, issue the following commands:

  1. `RDEFINE MFADEF MFABYPASS.USERID.<chinuser>`

     where `<chinuser>` is the channel initiator address space level user Id (associated with the channel initiator through the STC class)
  2. `PERMIT MFABYPASS.USERID.<chinuser> ACCESS(READ) ID(<explorer user>)`

  For more information on this approach, see Bypassing IBM MFA for applications.

- Use Out-of-band support on MFA, which was introduced with IBM MFA 1.2. With this approach, you pre-authenticate to the IBM MFA web server, and in addition to your user ID and password, specify additional authentication as determined through the policy. IBM MFA server generates a cache token credential that you then specify on the MQ Explorer authentication dialogue. The security administrator can allow this credential to be replayed for a reasonable period of time, so enabling normal MQ Explorer use.

For more information on this approach see Introduction to IBM MFA.

IBM MQ for z/OS security management

IBM MQ uses an in-storage table to hold information relating to each user and the access requests made by each user. To manage this table efficiently and to reduce the number of requests made from IBM MQ to the external security manager (ESM), a number of controls are available.

These controls are available through both the operations and control panels and IBM MQ commands.

User ID reverification

If the RACF definition of a user who is using IBM MQ resources has been changed, for example by connecting the user to a new group, you can tell the queue manager to sign this user on again the next time it tries to access an IBM MQ resource. You can do this by using the IBM MQ command RVERIFY SECURITY.

- User HX0804 is getting and putting messages to the PAYROLL queues on queue manager PRD1. However HX0804 now requires access to some of the PENSION queues on the same queue manager (PRD1).
- The data security administrator connects user HX0804 to the RACF group that allows access to the PENSION queues.
- So that HX0804 can access the PENSION queues immediately - that is, without shutting down queue manager PRD1, or waiting for HX0804 to time out - you must use the IBM MQ command:

```
RVERIFY SECURITY(HX0804)
```

Note: If you turn off user ID timeout for long periods of time (days or even weeks) while the queue manager is running, you must remember to run the RVERIFY SECURITY command for any users that have been revoked or deleted in that time.

User ID timeouts

You can make IBM MQ sign a user off a queue manager after a period of inactivity.

When a user accesses an IBM MQ resource, the queue manager tries to sign this user on to the queue manager (if subsystem security is active). This means that the user is authenticated to the ESM. This user remains signed on to IBM MQ until either the queue manager is shut down, or until the user ID is *timed out* (the authentication lapses) or reverified (reauthenticated).

When a user is timed out, the user ID is *signed off* within the queue manager and any security-related information retained for this user is discarded. The signing on and off of the user within the queue manager is not apparent to the application program or to the user.

Users are eligible for timeout when they have not used any IBM MQ resources for a predetermined amount of time. This time period is set by the MQSC ALTER SECURITY command.

Two values can be specified in the ALTER SECURITY command:

TIMEOUT
The time period in minutes that an unused user ID and its associated resources can remain within the IBM MQ queue manager.

INTERVAL
The time period in minutes between checks for user IDs and their associated resources, to determine whether the *TIMEOUT* has expired.

For example, if the *TIMEOUT* value is 30 and the *INTERVAL* value is 10, every 10 minutes IBM MQ checks user IDs and their associated resources to determine whether any have not been used for 30 minutes. If a timed-out user ID is found, that user ID is signed off within the queue manager. If any timed-out resource information associated with non-timed-out user IDs is found, that resource information is discarded. If you do not want to time out user IDs, set the *INTERVAL* value to zero. However, if the *INTERVAL* value is zero, storage occupied by user IDs and their associated resources is not freed until you issue a **REFRESH SECURITY** or **RVERIFY SECURITY** command.

Tuning this value can be important if you have many one-off users. If you set small interval and timeout values, resources that are no longer required are freed.

Note: If you use values for *INTERVAL* or *TIMEOUT* other than the defaults, you must reenter the command at every queue manager startup. You can do this automatically by putting the **ALTER SECURITY** command in the CSQINP1 data set for that queue manager.

Refreshing queue manager security on z/OS

IBM MQ for z/OS caches RACF data to improve performance. When you change certain security classes, you must refresh this cached information. Refresh security infrequently, for performance reasons. You can also choose to refresh only SSL security information.

When a queue is opened for the first time (or for the first time since a security refresh) IBM MQ performs a RACF check to obtain the user's access rights and places this information in the cache. The cached data includes user IDs and resources on which security checking has been performed. If the queue is opened again by the same user, the presence of the cached data means that IBM MQ does not have to issue RACF checks, which improves performance. The action of a security refresh is to discard any cached security information and so force IBM MQ to make a new check against RACF. Whenever you add, change or delete a RACF resource profile that is held in the MQADMIN, MXADMIN, MQPROC, MXPROC, MQQUEUE, MXQUEUE, MQNLIST, MXNLIST, or MXTOPIC class, you must tell the queue managers that use this class to refresh the security information that they hold. To do this, issue the following commands:

- The RACF SETROPTS RACLIST(classname) REFRESH command to refresh at the RACF level.
- The IBM MQ REFRESH SECURITY command to refresh the security information held by the queue manager. This command needs to be issued by each queue manager that accesses the profiles that have changed. If you have a queue-sharing group, you can use the command scope attribute to direct the command to all the queue managers in the group.

If you are using generic profiles in any of the IBM MQ classes, you must also issue normal RACF refresh commands if you change, add, or delete any generic profiles. For example, SETROPTS GENERIC(classname) REFRESH.

However, if a RACF resource profile is added, changed or deleted, and the resource to which it applies has not yet been accessed (so no information is cached), IBM MQ uses the new RACF information without a REFRESH SECURITY command being issued.

If RACF auditing is turned on, (for example, by using the RACF RALTER AUDIT(access-attempt (audit_access_level)) command), no caching takes place, and therefore IBM MQ refers directly to the RACF dataspace for every check. Changes are therefore picked up immediately and REFRESH SECURITY is not necessary to access the changes. You can confirm whether RACF auditing is on by using the RACF RLIST command. For example, you could issue the command

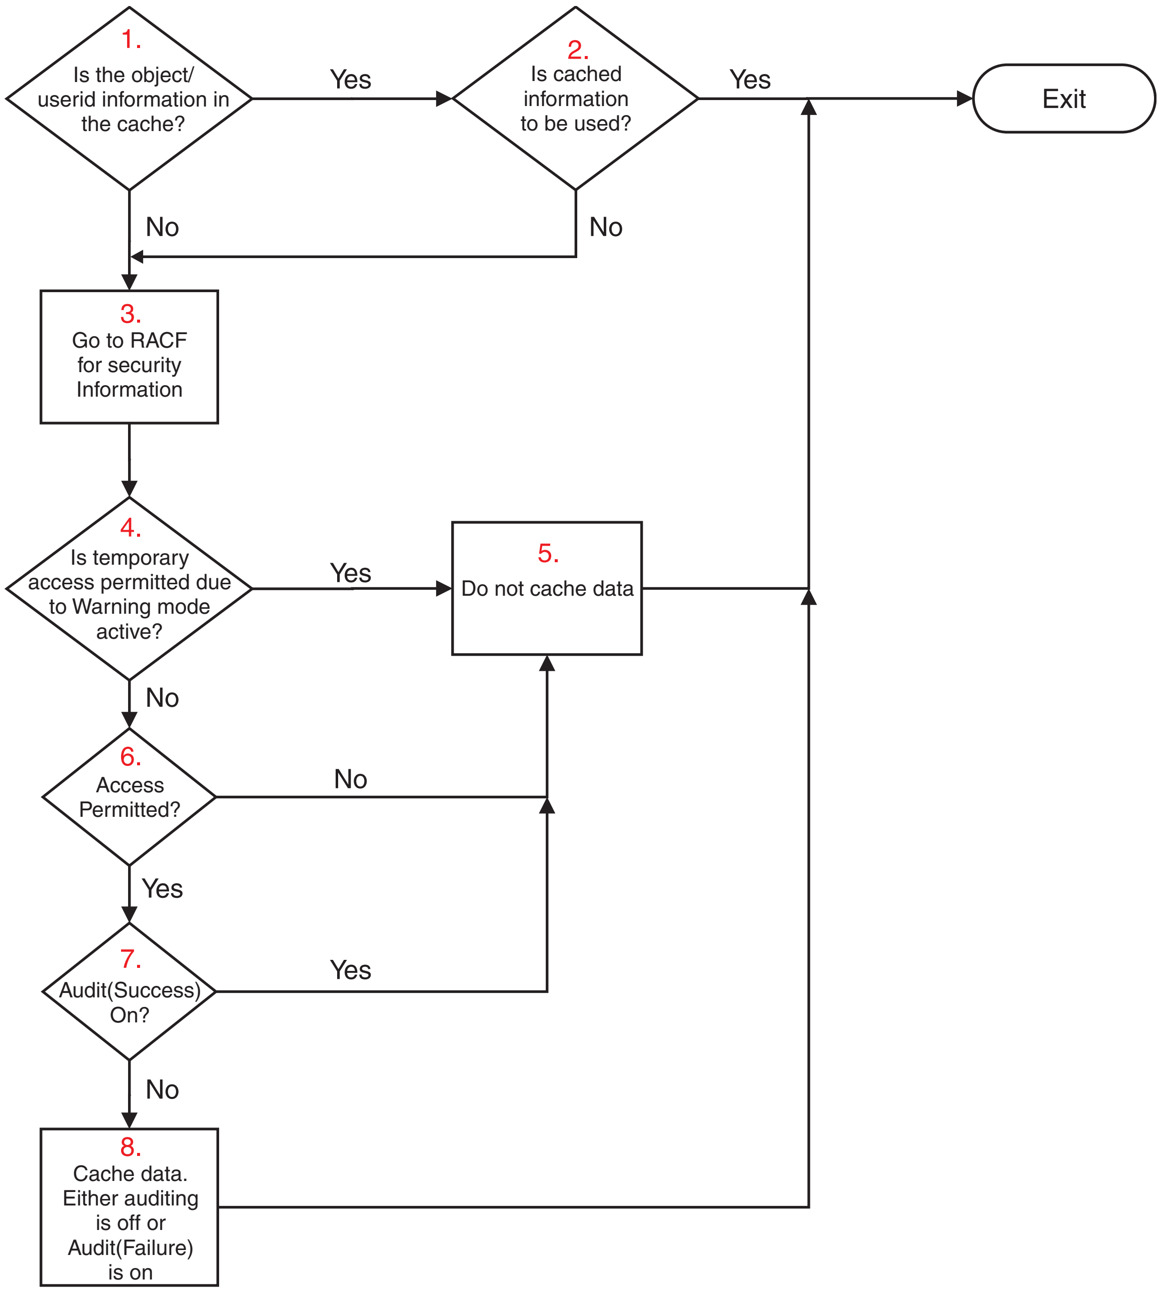
```
RLIST MQQUEUE (qmgr.SYSTEM.COMMAND.INPUT) GEN
```

and receive the results

```
CLASS      NAME
-----      ----
MQQUEUE    QP*.SYSTEM.COMMAND.*.** (G)
    AUDITING
    --------
    FAILURES(READ)
```

This indicates that auditing is set on. For more information, refer to the *z/OS Security Server RACF Auditor's Guide* and the *z/OS Security Server RACF Command Language Reference*.

Figure 70 on page 630 summarizes the situations in which security information is cached and in which cached information is used.



1.
Is the object/ userid information in the cache?
Yes
2.
Is cached information to be used?
Yes
Exit
No
No
3.
Go to RACF for security Information
4.
Is temporary access permitted due to Warning mode active?
Yes
5.
Do not cache data
No
6.
Access Permitted?
No
Yes
7.
Audit(Success) On?
Yes
No
8.
Cache data. Either auditing is off or Audit(Failure) is on

Figure 70. Logic flow for IBM MQ security caching

If you change your security settings by adding or deleting switch profiles in the MQADMIN or MXADMIN classes, use one of these commands to pick up these changes dynamically:

REFRESH SECURITY(*)

REFRESH SECURITY(MQADMIN)

REFRESH SECURITY(MXADMIN)

This means you can activate new security types, or deactivate them without having to restart the queue manager.

For performance reasons, these are the only classes affected by the REFRESH SECURITY command. You do *not* need to use REFRESH SECURITY if you change a profile in either the MQCONN or MQCMDS classes.

Note: A refresh of the MQADMIN or MXADMIN class is not required if you change a RESLEVEL security profile.

For performance reasons, use REFRESH SECURITY as infrequently as possible, ideally at off-peak times. You can minimize the number of security refreshes by connecting users to RACF groups that are already in the access list for IBM MQ profiles, rather than putting individual users in the access lists. In this way, you change the user rather than the resource profile. You can also RVERIFY SECURITY the appropriate user instead of refreshing security.

As an example of REFRESH SECURITY, suppose you define the new profiles to protect access to queues starting with INSURANCE.LIFE on queue manager PRMQ. You use these RACF commands:

```
RDEFINE MQQUEUE PRMQ.INSURANCE.LIFE.** UACC(NONE)
PERMIT PRMQ.INSURANCE.LIFE.** ID(LIFEGRP) ACCESS(UPDATE)
```

You must issue the following command to tell RACF to refresh the security information that it holds, for example:

```
SETROPTS RACLIST(MQQUEUE) REFRESH
```

Because these profiles are generic, you must tell RACF to refresh the generic profiles for MQQUEUE. For example:

```
SETROPTS GENERIC(MQQUEUE) REFRESH
```

Then you must use this command to tell queue manager PRMQ that the queue profiles have changed:

```
REFRESH SECURITY(MQQUEUE)
```

Refreshing SSL security

To refresh the cached view of the SSL Key Repository, issue the REFRESH SECURITY command with the option TYPE(SSL). This enables you to update some of your SSL settings without having to restart your channel initiator.

Displaying security status

To display the status of the security switches, and other security controls, issue the MQSC DISPLAY SECURITY command.

The following figure shows typical output of the DISPLAY SECURITY ALL command.

```
CSQH015I +CSQ1 Security timeout = 54 MINUTES
CSQH016I +CSQ1 Security interval = 12 MINUTES
CSQH030I +CSQ1 Security switches ...
CSQH034I +CSQ1 SUBSYSTEM: ON, 'SQ05.NO.SUBSYS.SECURITY' not found
CSQH032I +CSQ1 QMGR: ON, 'CSQ1.YES.QMGR.CHECKS' found
CSQH031I +CSQ1 QSG: OFF, 'SQ05.NO.QSG.CHECKS' found
CSQH031I +CSQ1 CONNECTION: OFF, 'CSQ1.NO.CONNECT.CHECKS' found
CSQH034I +CSQ1 COMMAND: ON, 'CSQ1.NO.COMMAND.CHECKS' not found
CSQH031I +CSQ1 CONTEXT: OFF, 'CSQ1.NO.CONTEXT.CHECKS' found
CSQH034I +CSQ1 ALTERNATE USER: ON, 'CSQ1.NO.ALTERNATE.USER.CHECKS' not found
CSQH034I +CSQ1 PROCESS: ON, 'CSQ1.NO.PROCESS.CHECKS' not found
CSQH034I +CSQ1 NAMELIST: ON, 'CSQ1.NO.NLIST.CHECKS' not found
CSQH034I +CSQ1 QUEUE: ON, 'CSQ1.NO.QUEUE.CHECKS' not found
CSQH034I +CSQ1 TOPIC: ON, 'CSQ1.NO.TOPIC.CHECKS' not found
CSQH031I +CSQ1 COMMAND RESOURCES: OFF, 'CSQ1.NO.CMD.RESC.CHECKS' found
CSQ9022I +CSQ1 CSQHPDTC ' DISPLAY SECURITY' NORMAL COMPLETION
```

Figure 71. Typical output from the DISPLAY SECURITY command

The example shows that the queue manager that replied to the command has subsystem, command, alternate user, process, namelist, and queue security active at queue manager level but not at queue-sharing group level. Connection, command resource, and context security are not active. It also shows that user ID timeouts are active, and that every 12 minutes the queue manager checks for user IDs that have not been used in this queue manager for 54 minutes and removes them.

Note: This command shows the current security status. It does not necessarily reflect the current status of the switch profiles defined to RACF, or the status of the RACF classes. For example, the switch profiles might have been changed since the last restart of this queue manager or REFRESH SECURITY command.

Security installation tasks for z/OS

After installing and customizing IBM MQ, authorize started task procedures to RACF, authorize access to various resources, and set up RACF definitions. Optionally, configure your system for SSL.

When IBM MQ is first installed and customized, you must perform these security-related tasks:

1. Set up IBM MQ data set and system security by:
   - Authorizing the queue manager started-task procedure xxxxMSTR and the distributed queuing started-task procedure xxxxCHIN to run under RACF.
   - Authorizing access to queue manager data sets.
   - Authorizing access to resources for those user IDs that will use the queue manager and utility programs.
   - Authorizing access for those queue managers that will use the coupling facility list structures.
   - Authorizing access for those queue managers that will use Db2.
2. Set up RACF definitions for IBM MQ security.
3. If you want to use the Secure Sockets Layer (SSL), prepare your system to use certificates and keys.

Setting up IBM MQ for z/OS data set security

There are many types of IBM MQ user. Use RACF to control their access to system data sets.

The possible users of IBM MQ data sets include the following entities:

- The queue manager itself.
- The channel initiator
- IBM MQ administrators, who need to create IBM MQ data sets, run utility programs, and similar tasks.
- Application programmers who need to use the IBM MQ-supplied copybooks, include data sets, macros, and similar resources.
- Applications involving one or more of:
  - Batch jobs
  - TSO users
  - CICS regions
  - IMS regions
- Data sets CSQOUTX and CSQSNAP
- Dynamic queues SYSTEM.CSQXCMD.*

For all these potential users, protect the IBM MQ data sets with RACF.

You must also control access to all your 'CSQINP' data sets.

RACF authorization of started-task procedures:

Some IBM MQ data sets are for the exclusive use of the queue manager. If you protect your IBM MQ data sets using RACF, you must also authorize the queue manager started-task procedure xxxxMSTR, and the distributed queuing started-task procedure xxxxCHIN, using RACF. To do this, use the STARTED class. Alternatively, you can use the started procedures table (ICHRIN03), but then you must perform an IPL of your z/OS system before the changes take effect.

For more information, see the *z/OS Security Server RACF System Programmer's Guide*.

The RACF user ID identified must have the required access to the data sets in the started-task procedure. For example, if you associate a queue manager started task procedure called CSQ1MSTR with the RACF user ID QMGRCSQ1, the user ID QMGRCSQ1 must have access to the z/OS resources accessed by the CSQ1 queue manager.

Also, the content of the GROUP field in the user ID of the queue manager must be the same as the content of the GROUP field in the STARTED profile for that queue manager. If the content in each GROUP field does not match then the appropriate user ID is prevented from entering the system. This situation causes IBM MQ to run with an undefined user ID and consequently close due to a security violation.

The RACF user IDs associated with the queue manager and channel initiator started task procedures must not have the TRUSTED attribute set.

Authorizing access to data sets:

The IBM MQ data sets should be protected so that no unauthorized user can run a queue manager instance, or gain access to any queue manager data. To do this, use normal z/OS RACF data set protection.

Table 74 summarizes the RACF access that the queue manager started task procedure must have to the different data sets.

Table 74. RACF access to data sets associated with a queue manager

RACF access	Data sets
READ	• thlqual.SCSQAUTH and thlqual.SCSQANLx (where x is the language letter for your national language). • The data sets referred to by CSQINP1, CSQINP2 and CSQXLIB in the queue manager's started task procedure.
UPDATE	• All page sets and log and BSDS data sets.
ALTER	• All archive log data sets.

Table 75 on page 634 summarizes the RACF access that the started task procedure for distributed queuing must have to the different data sets.

Table 75. RACF access to data sets associated with distributed queuing

RACF access	Data sets
READ	• thlqual.SCSQAUTH, thlqual.SCSQANLx (where x is the language letter for your national language), and thlqual.SCSQMVR1. • LE library data sets. • The data sets referred to by CSQXLIB and CSQINPX in the distributed queuing started task procedure.
UPDATE	• Data sets CSQOUTX and CSQSNAP

For more information, see the *z/OS Security Server RACF Security Administrator's Guide*.

Setting up IBM MQ for z/OS resource security

There are many types of IBM MQ user. Use RACF to control their access to IBM MQ resources.

The possible users of IBM MQ resources, such as queues and channels include the following entities:

- The queue manager itself.
- The channel initiator
- IBM MQ administrators, who need to create IBM MQ data sets, run utility programs, and similar tasks
- Application programmers who need to use the IBM MQ-supplied copybooks, include data sets, macros, and similar resources.
- Applications involving one or more of:
  - Batch jobs
  - TSO users
  - CICS regions
  - IMS regions
- Data sets CSQOUTX and CSQSNAP
- Dynamic queues SYSTEM.CSQXCMD.*

For all these potential users, protect the IBM MQ resources with RACF. In particular, note that the channel initiator needs access to various resources, as described in "Security considerations for the channel initiator on z/OS" on page 641, and so the user ID under which it runs must be authorized to access these resources.

If you are using a queue-sharing group, the queue manager might issue various commands internally, so the user ID it uses must be authorized to issue such commands. The commands are:

- DEFINE, ALTER, and DELETE for every object that has QSGDISP(GROUP)
- START and STOP CHANNEL for every channel used with CHLDISP(SHARED)

Configuring your z/OS system to use the Secure Sockets Layer (SSL)

z/OS

Use this topic as example of how to configure IBM MQ for z/OS with SSL using RACF commands.

If you want to use SSL for channel security, there are a number of tasks you need to perform on your system. (For details on using RACF commands for certificates and key repositories (key rings), see Working with SSL or TLS on z/OS .)

1. Create a key ring in RACF to hold all the keys and certificates for your system, using the RACF RACDCERT command. For example:

```
RACDCERT ID(CHINUSER) ADDRING(QM1RING)
```

   The ID must be either the channel initiator address space user ID or the user ID you want to own the key ring if it is to be a shared key ring.

2. Create a digital certificate for each queue manager, using the RACF RACDCERT command.

   The label of the certificate must be either the value of the IBM MQ **CERTLABL** attribute, if it is set, or the default `ibmWebSphereMQ` with the name of the queue manager or queue-sharing group appended. See Digital certificate labels for details. In this example it is `ibmWebSphereMQQM1`.

   For example:

```
RACDCERT ID(USERID) GENCERT
SUBJECTSDN(CN('username') O('IBM') OU('departmentname') C('England'))
WITHLABEL('ibmWebSphereMQQM1')
```

3. Connect the certificate in RACF to the key ring, using the RACF RACDCERT command. For example:

```
RACDCERT CONNECT(ID(USERID) LABEL('ibmWebSphereMQQM1') RING(QM1RING))
CONNECT ID(CHINUSER)
```

   You also need to connect any relevant signer certificates (from a certificate authority) to the key ring. That is, all certificate authorities for the SSL certificate of this queue manager and all certificate authorities for all SSL certificates that this queue manager communicates with. For example:

```
RACDCERT ID(CHINUSER)
CONNECT(CERTAUTH LABEL('My CA') RING(QM1RING) USAGE(CERTAUTH))
```

4. On each of your queue managers, use the IBM MQ ALTER QMGR command to specify the key repository that the queue manager needs to point to. For example, if the key ring is owned by the channel initiator address space:

```
ALTER QMGR SSLKEYR(QM1RING)
```

or if you are using a shared key ring:

```
ALTER QMGR SSLKEYR(userid/QM1RING)
```

where *userid* is the user ID that owns the shared key ring.

5. Certificate Revocation Lists (CRLs) allow the certificate authorities to revoke certificates that can no longer be trusted. CRLs are stored in LDAP servers. To access this list on the LDAP server, you first need to create an AUTHINFO object of AUTHTYPE CRLLDAP, using the IBM MQ DEFINE AUTHINFO command. For example:

```
DEFINE AUTHINFO(LDAP1)
AUTHTYPE(CRLLDAP)
CONNAME(ldap.server(389))
LDAPUSER('')
LDAPPWD('')
```

   In this example, the certificate revocation list is stored in a public area of the LDAP server, so the LDAPUSER and LDAPPWD fields are not necessary.

   Next, put your AUTHINFO object into a namelist, using the IBM MQ DEFINE NAMELIST command. For example:

```
DEFINE NAMELIST(LDAPNL) NAMES(LDAP1)
```

   Finally, associate the namelist with each queue manager, using the IBM MQ ALTER QMGR command. For example:

```
ALTER QMGR SSLCRLNL(LDAPNL)
```

6. Set up your queue manager to run SSL calls, using the IBM MQ ALTER QMGR command. This defines server subtasks that handle SSL calls only, which leaves the normal dispatchers to continue processing as normal without being affected by any SSL calls. You must have at least two of these subtasks. For example:

```
ALTER QMGR SSLTASKS(8)
```

   This change only takes effect when the channel initiator is restarted.

7. Specify the cipher specification to be used for each channel, using the IBM MQ DEFINE CHANNEL or ALTER CHANNEL command. For example:

```
ALTER CHANNEL(LDAPCHL)
CHLTYPE(SDR)
SSLCIPH(TLS_RSA_WITH_AES_128_CBC_SHA)
```

Both ends of the channel must specify the same cipher specification.

Managing channel authentication records in a queue-sharing group

Channel authentication records apply to the queue manager that they are created on, they are not shared throughout the queue-sharing group. Therefore if all the queue managers in the queue sharing group are required to have the same rules, some management needs to be carried out to keep all the rules the consistent.

1. Always add the `CMDSCOPE(*)` option to all `SET CHLAUTH` commands. This will send the command to all running queue managers in the queue-sharing group
2. Use the `DISPLAY CHLAUTH` command with the `CMDSCOPE(*)` option and then analyze the responses to see if the records are the same from all queue managers. When an inconsistency is found a `SET CHLAUTH` command can be issued containing the same rule with `CMDSCOPE(*)` or `CMDSCOPE(`*`qmgr-name`*`)`.
3. Add a member to the queue manager's CSQINP2 concatenation (see Initialization commands for details) that has the full set of rules. These will be read as part of the queue manager's initialization process. If the `SET CHLAUTH` command uses `ACTION(ADD)` the rule will only be added if it didn't exist. Using `ACTION(REPLACE)` will replace an existing rule if it already exists or add it if it does not. The same member could then be placed in the CSQINP2 concatenation of all queue managers in the queue-sharing group.
4. Use the CSQUTIL utility (see Issuing commands to IBM MQ (COMMAND) for details) to extract the rules from one queue manager using either the `MAKEDEF` or `MAKEREP` option. Then replay the output using CSQUTIL into the target queue manager.

Related concepts:

Channel authentication records
To exercise more precise control over the access granted to connecting systems at a channel level, you can use channel authentication records.

Auditing considerations on z/OS

The normal RACF auditing controls are available for conducting a security audit of a queue manager. IBM MQ does not gather any security statistics of its own. The only statistics are those that can be created by auditing.

RACF auditing can be based upon:

- User IDs
- Resource classes
- Profiles

For more details, see the *z/OS Security Server RACF Auditor's Guide*.

Note: Auditing degrades performance; the more auditing you implement, the more performance is degraded. This is also a consideration for the use of the RACF WARNING option.

Auditing RESLEVEL

Use the RESAUDIT system parameter to control the production of RESLEVEL audit records. RACF GENERAL audit records are produced.

Produce RESLEVEL audit records by setting the RESAUDIT system parameter to YES. If the RESAUDIT parameter is set to NO, audit records are not produced. For more details about setting this parameter, see Using CSQ6SYSP.

If RESAUDIT is set to YES, no normal RACF audit records are taken when the RESLEVEL check is made to see what access an address space user ID has to the hlq.RESLEVEL profile. Instead, IBM MQ requests that RACF create a GENERAL audit record (event number 27). These checks are only carried out at connect time, so the performance cost is minimal.

You can report the IBM MQ general audit records using the RACF report writer (RACFRW). You could use the following RACFRW commands to report the RESLEVEL access:

```
RACFRW
SELECT PROCESS
EVENT GENERAL
LIST
END
```

A sample report from RACFRW, excluding the `Date`, `Time`, and `SYSID` fields, is shown in Figure 72.

```
       RACF REPORT - LISTING OF PROCESS RECORDS                                     PAGE   4
                                  E
                                  V  Q
                                  E  U
*JOB/USER *STEP/  --TERMINAL--  N  A
   NAME    GROUP     ID    LVL  T  L

 WS21B    MQMGRP IGJZM000   0   27 0  JOBID=(WS21B 05.111 09:44:57),USERDATA=()
    TRUSTED USER                      AUTH=(NONE),REASON=(NONE)
                                   SESSION=TSOLOGON,TERMINAL=IGJZM000,
                                   LOGSTR='CSQH RESLEVEL CHECK PERFORMED AGAINST PROFILE(QM66.RESLEVEL),
                                   CLASS(MQADMIN), ACCESS EQUATES TO (CONTROL)',RESULT=SUCCESS,MQADMIN
```

Figure 72. Sample output from RACFRW showing RESLEVEL general audit records

From checking the LOGSTR data in this sample output, you can see that TSO user WS21B has CONTROL access to QM66.RESLEVEL. This means that all resource security checks are bypassed when user WS21B access QM66 resources.

For more information about using RACFRW, see the *z/OS Security Server RACF Auditor's Guide*.

Customizing security

If you want to change the way IBM MQ security operates, you must do this through the SAF exit (ICHRFR00), or exits in your external security manager.

To find out more about RACF exits, see the *z/OS Security Server RACROUTE Macro Reference* manual.

Note: Because IBM MQ optimizes calls to the ESM, RACROUTE requests might not be made on, for example, every open for a particular queue by a particular user.

Security violation messages on z/OS

A security violation is indicated by the return code MQRC_NOT_AUTHORIZED in an application program or by a message in the job log.

A return code of MQRC_NOT_AUTHORIZED can be returned to an application program for the following reasons:

- A user is not allowed to connect to the queue manager. In this case, you get an ICH408I message in the Batch/TSO, CICS, or IMS job log.
- A user sign-on to the queue manager has failed because, for example, the job user ID is not valid or appropriate, or the task user ID or alternate user ID is not valid. One or more of these user IDs might not be valid because they have been revoked or deleted. In this case, you get an ICHxxxx message and possibly an IRRxxxx message in the queue manager job log giving the reason for the sign-on failure. For example:

  ```
  ICH408I USER(NOTDFND ) GROUP(        ) NAME(???                 )
    LOGON/JOB INITIATION - USER AT TERMINAL          NOT RACF-DEFINED
  IRR012I  VERIFICATION FAILED. USER PROFILE NOT FOUND
  ```
- An alternate user has been requested, but the job or task user ID does not have access to the alternate user ID. For this failure, you get a violation message in the job log of the relevant queue manager.
- A context option has been used or is implied by opening a transmission queue for output, but the job user ID or, where applicable, the task or alternate user ID does not have access to the context option. In this case, a violation message is put in the job log of the relevant queue manager.
- An unauthorized user has attempted to access a secured queue manager object, for example, a queue. In this case, an ICH408I message for the violation is put in the job log of the relevant queue manager. This violation might be due to the job or, when applicable, the task or alternate user ID.

Violation messages for command security and command resource security can also be found in the job log of the queue manager.

If the ICH408I violation message shows the queue manager jobname rather than a user ID, this is normally the result of a blank alternate user ID being specified. For example:

```
ICH408I JOB(MQS1MSTR) STEP(MQS1MSTR)
         MQS1.PAYROLL.REQUEST CL(MQQUEUE)
         INSUFFICIENT ACCESS AUTHORITY
         ACCESS INTENT(UPDATE )  ACCESS ALLOWED(NONE   )
```

You can find out who is allowed to use blank alternate user IDs by checking the access list of the MQADMIN profile hlq.ALTERNATE.USER.-BLANK-.

An ICH408I violation message can also be generated by:

- A command being sent to the system-command input queue without context. User-written programs that write to the system-command input queue should always use a context option. For more information, see "Profiles for context security" on page 598.

- When the job accessing the IBM MQ resource does not have a user ID associated with it, or when an IBM MQ adapter cannot extract the user ID from the adapter environment.

Violation messages might also be issued if you are using both queue-sharing group and queue manager level security. You might get messages indicating that no profile has been found at queue manager level, but still be granted access because of a queue-sharing group level profile.

```
ICH408I JOB(MQS1MSTR) STEP(MQS1MSTR)
         MQS1.PAYROLL.REQUEST CL(MQQUEUE)
         PROFILE NOT FOUND - REQUIRED FOR AUTHORITY CHECKING
         ACCESS INTENT(UPDATE )  ACCESS ALLOWED(NONE   )
```

What to do if access is allowed or disallowed incorrectly

In addition to the steps detailed in the *z/OS Security Server RACF Security Administrator's Guide*, use this checklist if access to a resource appears to be incorrectly controlled.

- Are the switch profiles correctly set?
  - Is RACF active?
  - Are the IBM MQ RACF classes installed and active?

    Use the RACF command, SETROPTS LIST, to check this.
  - Use the IBM MQ DISPLAY SECURITY command to display the current switch status from the queue manager.
  - Check the switch profiles in the MQADMIN class.

    Use the RACF commands, SEARCH and RLIST, for this.
  - Recheck the RACF switch profiles by issuing the IBM MQ REFRESH SECURITY(MQADMIN) command.
- Has the RACF resource profile changed? For example, has universal access on the profile changed or has the access list of the profile changed?
  - Is the profile generic?

    If it is, issue the RACF command, SETROPTS GENERIC(classname) REFRESH.
  - Have you refreshed the security on this queue manager?

    If required, issue the RACF command SETROPTS RACLIST(classname) REFRESH.

    If required, issue the IBM MQ REFRESH SECURITY(*) command.
- Has the RACF definition of the user changed? For example, has the user been connected to a new group or has the user access authority been revoked?
  - Have you reverified the user by issuing the IBM MQ RVERIFY SECURITY(userid) command?
- Are security checks being bypassed due to RESLEVEL?
  - Check the connecting user ID's access to the RESLEVEL profile. Use the RACF audit records to determine what the RESLEVEL is set to.
  - For channels, remember that the access level that the channel initiator's userid has to RESLEVEL is inherited by all channels, so an access level, such as ALTER, that causes all checks to be bypassed causes security checks to be bypassed for all channels.
  - If you are running from CICS, check the transaction's RESSEC setting.
  - If RESLEVEL has been changed while a user is connected, they must disconnect and reconnect before the new RESLEVEL setting takes effect.
- Are you using queue-sharing groups?
  - If you are using both queue-sharing group and queue manager level security, check that you have defined all the correct profiles. If queue manager profile is not defined, a message is sent to the log stating that the profile was not found.

– Have you used a combination of switch settings that is not valid so that full security checking has been set on?
– Do you need to define security switches to override some of the queue-sharing group settings for your queue manager?
– Is a queue manager level profile taking precedence over a queue-sharing group level profile?

Security considerations for the channel initiator on z/OS

If you are using resource security in a distributed queuing environment, the Channel initiator address space needs appropriate access to various IBM MQ resources. You can use the Integrated Cryptographic Support Facility (ICSF) to seed the password protection algorithm.

Using resource security

If you are using resource security, consider the following points if you are using distributed queuing:

System queues
The channel initiator address space needs RACF UPDATE access to the system queues listed at "System queue security" on page 588, and to all the user destination queues and the dead-letter queue (but see "Dead-letter queue security" on page 587).

Transmission queues
The channel initiator address space needs ALTER access to all the user transmission queues.

Context security
The channel user ID (and the MCA user ID if one has been specified) need RACF CONTROL access to the hlq.CONTEXT.queuename profiles in the MQADMIN class. Depending on the RESLEVEL profile, the channel user ID might also need CONTROL access to these profiles.

All channels need CONTROL access to the MQADMIN hlq.CONTEXT. dead-letter-queue profile. All channels (whether initiating or responding) can generate reports, and consequently they need CONTROL access to the hlq.CONTEXT.reply-q profile.

SENDER, CLUSSDR, and SERVER channels need CONTROL access to the hlq.CONTEXT.xmit-queue-name profiles since messages can be put onto the transmission queue to wake up the channel to end gracefully.

Note: If the channel user ID, or a RACF group to which the channel user ID is connected, has CONTROL or ALTER access to the hlq.RESLEVEL, then there are no resource checks for the channel initiator or any of its channels.

See "Profiles for context security" on page 598 "RESLEVEL and the channel initiator connection" on page 615 and "User IDs for security checking" on page 617 for more information.

CSQINPX
If you are using the CSQINPX input data set, the channel initiator also needs READ access to CSQINPX, and UPDATE access to data set CSQOUTX and dynamic queues SYSTEM.CSQXCMD.*.

Connection security
The channel initiator address space connection requests use a connection type of CHIN, for which appropriate access security must be set, see "Connection security profiles for the channel initiator" on page 581.

Data sets
The channel initiator address space needs appropriate access to queue manager data sets, see "Authorizing access to data sets" on page 633.

Commands

The distributed queuing commands (for example, DEFINE CHANNEL, START CHINIT, START LISTENER, and other channel commands) must have appropriate command security set, see Table 59 on page 601.

If you are using a queue-sharing group, the channel initiator might issue various commands internally, so the user ID it uses must be authorized to issue such commands. These commands are START and STOP CHANNEL for every channel used with CHLDISP(SHARED).

If the PSMODE of the queue manager is not DISABLED, the channel initiator must have READ access to the DISPLAY PUBSUB command.

Channel security

Channels, particularly receivers and server-connections, need appropriate security to be set up; see "User IDs for security checking" on page 617 for more information.

You can also use the Transport Layer Security (TLS) or Secure Sockets Layer (SSL) protocols to provide security on channels. See "SSL and TLS security protocols in IBM MQ" on page 397 for more information about using TLS and SSL with IBM MQ.

See also "Access control for clients" on page 467 for information about server-connection security.

User IDs

The user IDs described in "User IDs used by the channel initiator" on page 620 and "User IDs used by the intra-group queuing agent" on page 624 need the following access:

- RACF UPDATE access to the appropriate destination queues and the dead-letter queue
- RACF CONTROL access to the `hlq.CONTEXT.queuename` profile if context checking is performed at the receiver
- Appropriate access to the hlq.ALTERNATE.USER.userid profiles they might need to use.
- For clients, the appropriate RACF access to the resources to be used.

APPC security

Set appropriate APPC security if you are using the LU 6.2 transmission protocol. (Use the APPCLU RACF class for example.) For information about setting up security for APPC, see the following manuals:

- *z/OS V1R2.0 MVS Planning: APPC Management*
- *Multiplatform APPC Configuration Guide*, an IBM Redbooks publication

Outbound transmissions use the "SECURITY(SAME)" APPC option. As a result, the user ID of the channel initiator address space and its default profile (RACF GROUP) are flowed across the network to the receiver with an indicator that the user ID has already been verified (ALREADYV).

If the receiving side is also z/OS, the user ID and profile are verified by APPC and the user ID is presented to the receiver channel and used as the channel user ID.

In an environment where the queue manager is using APPC to communicate with another queue manager on the same or another z/OS system, you need to ensure that either:

- The VTAM definition for the communicating LU specifies SETACPT(ALREADYV)
- There is a RACF APPCLU profile for the connection between LUs that specifies CONVSEC(ALREADYV)

Changing security settings

If the RACF access level that either the channel user ID or MCA user ID has to a destination queue is changed, this change takes effect only for new object handles (that is, new **MQOPEN** s) for the destination queue. The times when MCAs open and close queues is variable; if a channel is already running when such an access change is made, the MCA can continue to put messages on the destination queue using the existing security access of the user IDs rather than the updated security access. Stopping and restarting the channels to enforce the updated access level avoids this scenario.

Automatic restart
: If you are using the z/OS Automatic Restart Manager (ARM) to restart the channel initiator, the user ID associated with the XCFAS address space must be authorized to issue the IBM MQ START CHINIT command.

Using the Integrated Cryptographic Service Facility (ICSF)

The channel initiator can use ICSF to generate a random number when seeding the password protection algorithm to obfuscate passwords flowing over client channels if SSL/TLS is not being used. The process of generating a random number is called *entropy*.

If you have the z/OS feature installed but have not started ICSF, you see message CSQX213E and the channel initiator uses STCK for entropy.

Message CSQX213E warns you that the password protection algorithm is not as secure as it could be. However, you can continue your process; there is no other impact on runtime.

If you do not have the z/OS feature installed, the channel initiator automatically uses STCK.

Notes:
1. Using ICSF for entropy generates more random sequences than using STCK.
2. If you start ICSF you must restart the channel initiator.
3. ICSF is required for certain CipherSpecs. If you attempt to use one of these CipherSpecs and you do not have ICSF installed, you receive message CSQX629E.

Security in queue manager clusters on z/OS

Security considerations for clusters are the same for queue managers and channels that are not clustered. The channel initiator needs access to some additional system queues, and some additional commands need appropriate security set.

You can use the MCA user ID, channel authentication records, SSL or TLS, and security exits to authenticate cluster channels (as with conventional channels). The channel authentication records or security exit relating to the cluster-receiver channel must check that the remote queue manager is permitted access to the server queue manager's cluster queues. You can start to use IBM MQ cluster support without changing your existing queue access security. You must, however, allow other queue managers in the cluster to write to the SYSTEM.CLUSTER.COMMAND.QUEUE if they are to join the cluster.

IBM MQ cluster support does not provide a mechanism to limit a member of a cluster to the client role only. As a result, you must be sure that you trust any queue managers that you allow into the cluster. If any queue manager in the cluster creates a queue with a particular name, it can receive messages for that queue, regardless of whether the application putting messages to that queue intended this or not.

To restrict the membership of a cluster, take the same action that you would take to prevent queue managers connecting to receiver channels. You restrict the membership of a cluster by using channel authentication records or by writing a security exit program on the receiver channel. You can also write an exit program to prevent unauthorized queue managers from writing to the SYSTEM.CLUSTER.COMMAND.QUEUE.

Note: It is not advisable to permit applications to open the SYSTEM.CLUSTER.TRANSMIT.QUEUE directly. It is also not advisable to permit an application to open any other transmission queue directly.

If you are using resource security, consider the following points in addition to the considerations contained in “Security considerations for the channel initiator on z/OS” on page 641:

System queues
The channel initiator needs RACF ALTER access to the following system queues:
- SYSTEM.CLUSTER.COMMAND QUEUE
- SYSTEM.CLUSTER.TRANSMIT.QUEUE.

and UPDATE access to SYSTEM.CLUSTER.REPOSITORY.QUEUE

It also needs READ access to any namelists used for clustering.

Commands
Set appropriate command security (as described in Table 59 on page 601) for the cluster support commands (REFRESH and RESET CLUSTER, SUSPEND, and RESUME QMGR.

Security considerations for using IBM MQ with CICS

The CICS adapter provides information to IBM MQ for use in security.

The CICS adapter provides the following information to IBM MQ specifically for use in IBM MQ security:
- Whether CICS resource-level security is active for this transaction, as specified on the RESSEC or RSLC operand of the RDO TRANSACTION definition.
- User IDs.

  For terminal tasks where a user has not signed on, the user ID is the CICS user ID associated with the terminal and is either:
  - The default CICS user ID as specified on the CICS parameter DFLTUSER SIT
  - A preset security user ID specified on the terminal definition

  For non-terminal tasks, the CICS adapter tries to get a user ID with an EXEC CICS ASSIGN command. If this is unsuccessful, the adapter tries to get the user ID using EXEC CICS INQUIRE TASK. If security is active in CICS, and the non-terminal attached transaction is defined with CMDSEC(YES), the CICS adapter passes a user ID of blanks to IBM MQ.

For details of security considerations, see:
- Security for the CICS-IBM MQ adapter.
- Security for the CICS-IBM MQ bridge.

Controlling the security of CICS transactions supplied by IBM MQ

If you want a user to administer the CICS adapter, grant the user authorization to certain transactions.

The CKTI and CKAM transactions are designed to be run without a terminal; no user should have access to these transactions. These transactions are examples of what the *CICS RACF Security Guide* calls "category 2 transactions". For information about how to set up these transactions in CICS and RACF, see the information about category 2 transactions in the *CICS RACF Security Guide*.

If you want a user to administer the CICS adapter, you must grant the user authorization to these transactions:

CKQC	Controls the CICS adapter functions
CKBM	Controls the CICS adapter functions
CKRT	Controls the CICS adapter functions
CKCN	Connect
CKSD	Disconnect
CKRS	Statistics
CKDP	Full screen display
CKDL	Line mode display
CKSQ	CKTI START/STOP

If required, you can restrict access to specific functions of the adapter. For example, if you want to allow users to display the status of the adapter through the full screen interface, but nothing else, give them access to CKQC, CKBM, CKRT, and CKDP only.

Define these transactions to CICS with RESSEC(NO) and CMDSEC(NO). For more details, see the *CICS RACF Security Guide*.

The CICS adapter user ID

The user ID associated with the CICS adapter is that of the IBM MQ-supplied task initiator transaction, CKTI. This has a number of implications.

User ID checking for IBM MQ resources during PLTPI and PLTSD

If an IBM MQ resource is accessed during the CICS PLTPI phase, the user ID passed to IBM MQ is blanks. If an IBM MQ resource is accessed during the CICS PLTSD phase, the user ID passed to IBM MQ is the user ID associated with the shutdown transaction.

If CKTI is started during the CICS PLTPI phase, the user ID of the CKTI task is the CICS sysidnt. This means that a user ID with the same name as the CICS sysidnt must be defined and given access to the required IBM MQ resources, for example, initiation queues.

Terminal user IDs

If CKTI is started from a terminal from the CKQC transaction or a user-written program that links to CSQCSSQ, the user ID that CKTI uses is the same as the user ID of the terminal that started CKTI.

Automating starting of CKTI

To automate the starting of CKTIs under a specific user ID, you can use an automation product, for example, Tivoli® NetView® for z/OS. You can use this to sign on a CICS console and issue the STARTCKTI command.

You can also use preset security sequential terminals, which have been defined to emulate a CRLP terminal, with the sequential terminal input containing the CKQC STARTCKTI command.

However, when the CICS adapter alert monitor reconnects CICS to IBM MQ, after, for example, an IBM MQ restart, only the CKTI specified at the initial IBM MQ connection is restarted. You must automate starting any extra CKTIs yourself.

Propagating the CKTI user ID to other CICS transactions

If CKTI starts other CICS transactions, for example, message channel agents (MCAs) or user-written CICS applications, the user ID of CKTI is propagated to these applications. For example, if CKTI is running under user ID *USERNAME* and a trigger event occurs that requires the sender MCA transaction, *TRNA*, to be started, the *TRNA* transaction also runs under user ID *USERNAME*. Therefore user ID *USERNAME* must have access to the required transmission queue.

Security considerations for the CICS bridge

When you run the CICS bridge, you can specify the level of authentication you want to take place.

If requested, the bridge checks the user ID and password extracted from the IBM MQ request message before running the CICS program named in the request message. The queue manager uses the external security manager (ESM) (for example RACF) to do authentication. Therefore, user IDs in the request message must be defined to the ESM.

Note:

1. If you have not specified a user ID in the message descriptor (MQMD) or password in the CICS bridge header (MQCIH) of a message, the bridge task runs with the LOCAL level of authentication, even if you started the bridge monitor with a different authentication option.
2. The options that include password (or PassTicket) validation require an MQCIH to be provided. See MQCIH - CICS bridge header for more information about the MQCIH header.
3. PassTicket validation is performed using IBM MQ services, not EXEC CICS VERIFY, as the CICS service does not accept an APPLID.

The level of authentication you can use is described using the following keywords:

LOCAL
This is the default value. CICS programs run by the bridge task are started with the CICS DFLTUSER user ID, therefore run with the authority associated with this user ID. There is no checking of user IDs or passwords. If a CICS program is run that tries to access protected resources, it is likely to fail.

IDENTIFY
When you start the monitor task with the IDENTIFY authentication option, the bridge task is started with the user ID specified in the message (MQMD). CICS programs run by the bridge run with the user ID from the MQMD. There is no password checking, the user ID is treated as trusted.

VERIFY_UOW
If MQMD.PutApplType is set to MQAT_NO_CONTEXT, the CICS DFLTUSER user ID is used, as for the LOCAL authentication option. Otherwise, the bridge monitor checks the user ID (in the MQMD) and password (in the CIH) before starting the bridge task, and CICS programs run by the bridge run with the user ID extracted from the MQMD. If the user ID or password is invalid, the request fails with return code MQCRC_SECURITY_ERROR. Subsequent messages processed by this transaction are not checked.

Bridge tasks that cannot be started because of a security failure are tried again if ROUTEMEM=N (the default) is specified. However, if ROUTEMEM=Y is specified the bridge messages are put to the dead-letter queue.

VERIFY_ALL
This value is the same as VERIFY_UOW except that the bridge task checks the user ID and password in every message. This option is not applicable for 3270 transactions when using CICS earlier than CICS Transaction Server Version 2 Release 2.

A PassTicket can be used in place of a password to avoid the need to flow passwords in messages (see Security Server RACF System Programmer's Guide). When generating a PassTicket an APPLID must be specified. If you are using a single bridge monitor, the APPLID is the CICS APPLID unless a different value was specified when the bridge was started. If you are using multiple bridge monitors for a queue, you must specify the APPLID to be used, using the PASSTKTA= *applid* parameter at bridge startup.

If you have not specified a user ID in a message, or you have not provided a password, the CICS program started by the CICS bridge runs with the user ID set to the user ID used to start the bridge monitor, regardless of the option requested. If you want more than one level of authentication checking performed, run a monitor task for each level you need.

When a CICS DPL request is read by the bridge monitor it starts the transaction specified in the CICS bridge header (MQCIH) or, if no transaction is specified, transaction CKBP. The user IDs under which the bridge monitor runs must have authority to start the various transactions that might be requested. The default transaction ID for the CICS bridge monitor is CKBR but you can change this or define additional transaction IDs if you want more granular access to queues and transactions. You can use CICS surrogate security to restrict which user ID and transaction combinations a bridge monitor transaction and user ID can start.

Table 76 and Table 77 summarize the level of authority of the bridge monitor and the bridge tasks, and the use of the MQMD user ID.

Table 76. CICS bridge monitor security

Monitor started by	**At a signed on terminal**	**Monitor authority**
From a terminal or EXEC CICS LINK within a program	Yes	Signed on user ID
From a terminal or EXEC CICS LINK within a program	No	CICS default user ID
EXEC CICS START with user ID	-	User ID from START
EXEC CICS START without user ID	-	CICS default user ID
The IBM MQ trigger monitor CKTI	-	CICS default user ID

Table 77. CICS bridge task security

AUTH	**Bridge task authority**
LOCAL	CICS default user ID
IDENTIFY	MQMD UserIdentifier
VERIFY_UOW	MQMD UserIdentifier
VERIFY_ALL	MQMD UserIdentifier

The options IDENTIFY, VERIFY_UOW, and VERIFY_ALL need the user ID of the bridge monitor defined to RACF as a surrogate of all the user IDs used in request messages. This requirement is in addition to the user ID in the message being defined to RACF. (A surrogate user is one who has the authority to start work on behalf of another user, without knowing the other user's password.)

For more information about surrogate user security, see the *CICS RACF Security Guide*.

Note: When IDENTIFY security is being used, you might see abend AICO for CKBP if you try to run with a user ID that has been revoked. The error reply has return code MQCRC_BRIDGE_ERROR with reason MQFB_CICS_BRIDGE_FAILURE.

Authority for the CICS bridge:

Components of the bridge need authority to either put to or get from the various IBM MQ queues.

In summary, the required authority is as follows:
- The monitor and all bridge tasks need authority to get messages from the bridge request queue.
- A bridge task needs authority to put messages to its own reply-to queue.
- To ensure that any error replies are received, the monitor needs authority to put messages to all reply-to queues.
- Bridge tasks need authority to put messages to the dead-letter queue.
- The monitor needs authority to put messages to the dead-letter queue, unless you want the bridge to stop if an error occurs.
- The monitor and all bridge tasks need authority to put messages to the backout requeue queue, if one is defined

See Table 76 on page 647 to determine the correlation between user IDs and authority.

Security considerations for using IBM MQ with IMS

Use this topic to plan your security requirements when you use IBM MQ with IMS.

Using the OPERCMDS class

If you are using RACF to protect resources in the OPERCMDS class, ensure that the userid associated with your IBM MQ queue manager address space has authority to issue the MODIFY command to any IMS system to which it can connect.

Security considerations for the IMS bridge

There are four aspects that you must consider when deciding your security requirements for the IMS bridge, these are:
- What security authorization is needed to connect IBM MQ to IMS
- How much security checking is performed on applications using the bridge to access IMS
- Which IMS resources these applications are allowed to use
- What authority is to be used for messages that are put and got by the bridge

When you define your security requirements for the IMS bridge you must consider the following:
- Messages passing across the bridge might have originated from applications on platforms that do not offer strong security features
- Messages passing across the bridge might have originated from applications that are not controlled by the same enterprise or organization

Security considerations for connecting to IMS

Grant the user ID of the IBM MQ queue manager address space access to the OTMA group.

The IMS bridge is an OTMA client. The connection to IMS operates under the user ID of the IBM MQ queue manager address space. This is normally defined as a member of the started task group. This user ID must be granted access to the OTMA group (unless the /SECURE OTMA setting is NONE).

To do this, define the following profile in the FACILITY class:

```
IMSXCF.xcfgname.mqxcfmname
```

Where `xcfgname` is the XCF group name and `mqxcfmname` is the XCF member name of IBM MQ.

You must give your IBM MQ queue manager user ID read access to this profile.

Note:

1. If you change the authorities in the FACILITY class, you must issue the RACF command SETROPTS RACLIST(FACILITY) REFRESH to activate the changes.
2. If profile hlq.NO.SUBSYS.SECURITY exists in the MQADMIN class, no user ID is passed to IMS and the connection fails unless the /SECURE OTMA setting is NONE.

Application access control for the IMS bridge

Define a RACF profile in the FACILITY class for each IMS system. Grant an appropriate level of access to the IBM MQ queue manager user ID.

For each IMS system that the IMS bridge connects to, you can define the following RACF profile in the FACILITY class to determine how much security checking is performed for each message passed to the IMS system.

```
IMSXCF.xcfgname.imsxcfmname
```

Where `xcfgname` is the XCF group name and `imsxcfmname` is the XCF member name for IMS. (You need to define a separate profile for each IMS system.)

The access level you allow for the IBM MQ queue manager user ID in this profile is returned to IBM MQ when the IMS bridge connects to IMS, and indicates the level of security that is required on subsequent transactions. For subsequent transactions, IBM MQ requests the appropriate services from RACF and, where the user ID is authorized, passes the message to IMS.

OTMA does not support the IMS /SIGN command; however, IBM MQ allows you to set the access checking for each message to enable implementation of the necessary level of control.

The following access level information can be returned:

NONE or NO PROFILE FOUND
These values indicate that maximum security is required, that is, authentication is required for every transaction. A check is made to verify that the user ID specified in the *UserIdentifier* field of the MQMD structure, and the password or PassTicket in the *Authenticator* field of the MQIIH structure are known to RACF, and are a valid combination. A UTOKEN is created with a password or PassTicket, and passed to IMS ; the UTOKEN is not cached.

Note: If profile hlq.NO.SUBSYS.SECURITY exists in the MQADMIN class, this level of security overrides whatever is defined in the profile.

READ This value indicates that the same authentication is to be performed as for `NONE` under the following circumstances:

- The first time that a specific user ID is encountered
- When the user ID has been encountered before but the cached UTOKEN was not created with a password or PassTicket

IBM MQ requests a UTOKEN if required, and passes it to IMS.

Note: If a request to reverify security has been acted on, all cached information is lost and a UTOKEN is requested the first time each user ID is later encountered.

UPDATE
A check is made that the user ID in the *UserIdentifier* field of the MQMD structure is known to RACF.

A UTOKEN is built and passed to IMS ; the UTOKEN is cached.

CONTROL/ALTER
These values indicate that no security UTOKENs need to be provided for any user IDs for this IMS system. (You would probably only use this option for development and test systems.)

Attention: Note that the user ID contained in the *UserIdentifier* field of the MQMD structure is still passed for **`CONTROL/ALTER`**.

Note:
1. This access is defined when IBM MQ connects to IMS, and lasts for the duration of the connection. To change the security level, the access to the security profile must be changed and then the bridge stopped and restarted (for example, by stopping and restarting OTMA).
2. If you change the authorities in the FACILITY class, you must issue the RACF command SETROPTS RACLIST(FACILITY) REFRESH to activate the changes.
3. You can use a password or a PassTicket, but you must remember that the IMS bridge does not encrypt data. For information about using PassTickets, see "Using RACF PassTickets in the IMS header" on page 652.
4. Some of these results might be affected by security settings in IMS, using the /SECURE OTMA command.
5. Cached UTOKEN information is held for the duration defined by the INTERVAL and TIMEOUT parameters of the IBM MQ ALTER SECURITY command.
6. The RACF WARNING option has no effect on the IMSXCF.xcfgname.imsxcfmname profile. Its use does not affect the level of access granted, and no RACF WARNING messages are produced.

Security checking on IMS

Messages that pass across the bridge contain security information. The security checks made depend on the setting of the IMS command /SECURE OTMA.

Each IBM MQ message that passes across the bridge contains the following security information:
- A user ID contained in the *UserIdentifier* field of the MQMD structure
- The security scope contained in the *SecurityScope* field of the MQIIH structure (if the MQIIH structure is present)
- A UTOKEN (unless the IBM MQ sub system has CONTROL or ALTER access to the relevant `IMSXCF.xcfgname.imsxcfmname` profile)

The security checks made depend on the setting of the IMS command /SECURE OTMA, as follows:

/SECURE OTMA NONE
No security checks are made for the transaction.

/SECURE OTMA CHECK
The *UserIdentifier* field of the MQMD structure is passed to IMS for transaction or command authority checking.

An ACEE (Accessor Environment Element) is built in the IMS control region.

/SECURE OTMA FULL
The *UserIdentifier* field of the MQMD structure is passed to IMS for transaction or command authority checking.

An ACEE is built in the IMS dependent region as well as the IMS control region.

/SECURE OTMA PROFILE
The *UserIdentifier* field of the MQMD structure is passed to IMS for transaction or command authority checking

The *SecurityScope* field in the MQIIH structure is used to determine whether to build an ACEE in the IMS dependent region as well as the control region.

Note:

1. If you change the authorities in the TIMS or CIMS class, or the associated group classes GIMS or DIMS, you must issue the following IMS commands to activate the changes:
   - /MODIFY PREPARE RACF
   - /MODIFY COMMIT
2. If you do not use /SECURE OTMA PROFILE, any value specified in the *SecurityScope* field of the MQIIH structure is ignored.

Security checking done by the IMS bridge

Different authorities are used depending on the action being performed.

When the bridge puts or gets a message, the following authorities are used:

Getting a message from the bridge queue
No security checks are performed.

Putting an exception, or COA report message
Uses the authority of the user ID in the *UserIdentifier* field of the MQMD structure.

Putting a reply message
Uses the authority of the user ID in the *UserIdentifier* field of the MQMD structure of the original message

Putting a message to the dead-letter queue
No security checks are performed.

Note:

1. If you change the IBM MQ class profiles, you must issue the IBM MQ REFRESH SECURITY(*) command to activate the changes.
2. If you change the authority of a user, you must issue the MQSC RVERIFY SECURITY command to activate the change.

Using RACF PassTickets in the IMS header

You can use a PassTicket in place of a password in the IMS header.

If you want to use a PassTicket instead of a password in the IMS header (MQIIH), specify the application name against which the PassTicket is validated in the PASSTKTA attribute of the STGCLASS definition of the IMS bridge queue to which the message is to be routed.

If the PASSTKTA value is left blank, you must arrange to have a PassTicket generated. The application name in this case must be of the form MVSxxxx, where xxxx is the SMFID of the z/OS system on which the target queue manager runs.

A PassTicket is built from a user ID, the target application name, and a secret key. It is an 8-byte value containing uppercase alphabetic and numeric characters. It can be used only once, and is valid for a 20 minute period. If a PassTicket is generated by a local RACF system, RACF only checks that the profile exists and not that the user has authority against the profile. If the PassTicket was generated on a remote system, RACF validates the access of the user ID to the profile. For full information about PassTickets, see the *z/OS SecureWay Security Server RACF Security Administrator's Guide*.

PassTickets in IMS headers are given to RACF by IBM MQ, not IMS.

Setting up IBM MQ MQI client security

You must consider IBM MQ MQI client security, so that the client applications do not have unrestricted access to resources on the server.

When running a client application, do not run the application using a user ID that has more access rights than necessary; for example, a user in the `mqm` group or even the `mqm` user itself.

By running an application as a user with too many access rights, you run the risk of the application accessing and changing parts of the queue manager, either by accident or maliciously.

There are two aspects to security between a client application and its queue manager server: authentication and access control.

- Authentication can be used to ensure that the client application, running as a specific user, is who they say they are. By using authentication you can prevent an attacker from gaining access to your queue manager by impersonating one of your applications.

  From IBM MQ Version 8.0, authentication is provided by one of two options:
  - The connection authentication feature.

    For more information on connection authentication, see "Connection authentication" on page 430.
  - Using mutual authentication within SSL or TLS.

    For more information on SSL or TLS, see "Working with SSL or TLS" on page 658.
- Access control can be used to give or remove access rights for a specific user or group of users. By running a client application with a specifically created user (or user in a specific group) you can then use access controls to ensure the application cannot access parts of your queue manager that the application is not supposed to.

  When setting up access control you must consider channel authentication rules and the MCAUSER field on a channel. Both of these features have the ability to change which user id is being used for verifying access control rights.

  For more information on access control, see "Authorizing access to objects" on page 735.

If you have set up a client application to connect to a specific channel with a restricted ID, but the channel has an administrator ID set in its MCAUSER field then, provided the client application connects successfully, the administrator ID is used for access control checks. Therefore, the client application will have full access rights to your queue manager.

For more information on the MCAUSER attribute, see “Mapping a client asserted user ID to an MCAUSER user ID” on page 765.

Channel authentication rules can also be used as a method for controlling access to a queue manager, by setting up specific rules and criteria for a connection to be accepted.

For more information on channel authentication rules see: “Channel authentication records” on page 424.

Specifying that only FIPS-certified CipherSpecs are used at run time on the MQI client

Create your key repositories using FIPS-compliant software, then specify that the channel must use FIPS-certified CipherSpecs.

In order to be FIPS-compliant at run time, the key repositories must have been created and managed using only FIPS-compliant software such as runmqakm with the -fips option.

You can specify that an SSL or TLS channel must use only FIPS-certified CipherSpecs in three ways, listed in order of precedence:

1. Set the FipsRequired field in the MQSCO structure to MQSSL_FIPS_YES.
2. Set the environment variable MQSSLFIPS to YES.
3. Set the SSLFipsRequired attribute in the client configuration file to YES.

By default, FIPS-certified CipherSpecs is not required.

These values have the same meanings as the equivalent parameter values on ALTER QMGR SSLFIPS (see ALTER QMGR). If the client process currently has no active SSL or TLS connections, and a FipsRequired value is validly specified on an SSL MQCONNX, all subsequent SSL connections associated with this process must use only the CipherSpecs associated with this value. This applies until this and all other SSL or TLS connections have stopped, at which stage a subsequent MQCONNX can provide a new value for FipsRequired.

If cryptographic hardware is present, the cryptographic modules used by IBM MQ can be configured to be those modules provided by the hardware product, and these might be FIPS-certified to a particular level. The configurable modules and whether they are FIPS-certified depends on the hardware product in use.

Where possible, if FIPS-only CipherSpecs is configured then the MQI client rejects connections which specify a non-FIPS CipherSpec with MQRC_SSL_INITIALIZATION_ERROR. IBM MQ does not guarantee to reject all such connections and it is your responsibility to determine whether your IBM MQ configuration is FIPS-compliant.

Related concepts:

"Federal Information Processing Standards (FIPS) for UNIX, Linux, and Windows" on page 407
When cryptography is required on an SSL or TLS channel on Windows, UNIX and Linux systems, IBM MQ uses a cryptography package called IBM Crypto for C (ICC). On the Windows, UNIX and Linux platforms, the ICC software has passed the Federal Information Processing Standards (FIPS) Cryptomodule Validation Program of the US National Institute of Standards and Technology, at level 140-2.

SSL stanza of the client configuration file

Running SSL or TLS client applications with multiple installations of GSKit V8.0 on AIX

SSL or TLS client applications on AIX might experience `MQRC_CHANNEL_CONFIG_ERROR` and error `AMQ6175` when running on AIX systems with multiple GSKit V8.0 installations.

When running client applications on an AIX system with multiple GSKit V8.0 installations, the client connect calls can return `MQRC_CHANNEL_CONFIG_ERROR` when using SSL or TLS. The `/var/mqm/errors` logs record error `AMQ6175` and `AMQ9220` for the failing client application, for example:

```
09/08/11 11:16:13 - Process(24412.1) User(user) Program(example)
                    Host(machine.example.ibm.com) Installation(Installation1)
                    VRMF(7.1.0.0)
AMQ6175: The system could not dynamically load the shared library
'/usr/mqm/gskit8/lib64/libgsk8ssl_64.so'. The system returned
error number '8' and error message 'Symbol resolution failed
for /usr/mqm/gskit8/lib64/libgsk8ssl_64.so because:
    Symbol VALUE_EC_NamedCurve_secp256r1__9GSKASNOID (number 16) is not
exported from dependent module /db2data/db2inst1/sqllib/lib64/libgsk8cms_64.so.
    Symbol VALUE_EC_NamedCurve_secp384r1__9GSKASNOID (number 17) is not exported from
dependent module /db2data/db2inst1/sqllib/lib64/libgsk8cms_64.so.
    Symbol VALUE_EC_NamedCurve_secp521r1__9GSKASNOID (number 18) is not exported from
dependent module /db2data/db2inst1/sqllib/lib64/libgsk8cms_64.so.
    Symbol VALUE_EC_ecPublicKey__9GSKASNOID (number 19) is not exported from dependent
module /db2data/db2inst1/sqllib/lib64/libgsk8cms_64.so.
    Symbol VALUE_EC_ecdsa_with_SHA1__9GSKASNOID (number 20) is not exported from
dependent module /db2data/db2inst1/sqllib/lib64/libgsk8cms_64.so.
    Symbol VALUE_EC_ecdsa__9GSKASNOID (number 21) is not exported from dependent
      module /db2data/db2inst1/sqllib/lib64/libgsk8cms_64.so.'.

EXPLANATION:
This message applies to AIX systems. The shared library
'/usr/mqm/gskit8/lib64/libgsk8ssl_64.so' failed
to load correctly due to a problem with the library.
ACTION:
Check the file access permissions and that the file has not been corrupted.
----- amqxufnx.c : 1284 -------------------------------------------------------
09/08/11 11:16:13 - Process(24412.1) User(user) Program(example)
                    Host(machine.example.ibm.com) Installation(Installation1)
                    VRMF(7.1.0.0)
AMQ9220: The GSKit communications program could not be loaded.

EXPLANATION:
The attempt to load the GSKit library or procedure
'/usr/mqm/gskit8/lib64/libgsk8ssl_64.so' failed with error code
536895861.
ACTION:
Either the library must be installed on the system or the environment changed
to allow the program to locate it.
----- amqcgska.c : 836 --------------------------------------------------------
```

A common cause of this error is that the setting of the LIBPATH or LD_LIBRARY_PATH environment variable has caused the IBM MQ client to load a mixed set of libraries from two different GSKit V8.0 installations. Executing an IBM MQ client application in a Db2 environment can cause this error.

To avoid this error, include the IBM MQ library directories at the front of the library path so that the IBM MQ libraries take precedence. This can be achieved using the **setmqenv** command with the **-k** parameter, for example:

```
. /usr/mqm/bin/setmqenv -s -k
```

For more information about the use of the **setmqenv** command, refer to setmqenv (set IBM MQ environment)

Setting up communications for SSL or TLS on IBM i

IBM i

Secure communications that use the SSL or TLS cryptographic security protocols involve setting up the communication channels and managing the digital certificates that you will use for authentication.

To set up your SSL or TLS installation you must define your channels to use SSL or TLS. You must also create and manage your digital certificates. On some operating systems, you can perform the tests with self–signed certificates. However, on IBM i, you must use personal certificates signed by a local CA.

For full information about creating and managing certificates, see “Working with SSL or TLS on IBM i” on page 661.

This collection of topics introduces some of the tasks involved in setting up SSL or TLS communications, and provides step-by-step guidance on completing those tasks

You might also want to test SSL or TLS client authentication, which are optional parts of the SSL and TLS protocols. During the SSL or TLS handshake, the SSL or TLS client always obtains and validates a digital certificate from the server. With the IBM MQ implementation, the SSL or TLS server always requests a certificate from the client.

On IBM i, the SSL or TLS client sends a certificate only if it has one labeled in the correct IBM MQ format:

- For a queue manager, ibmwebspheremq followed by the name of your queue manager changed to lower case. For example, for QM1, ibmwebspheremqqm1.
- For an IBM MQ C Client for IBM i, ibmwebspheremq followed by your logon user ID changed to lower case, for example ibmwebspheremqmyuserid.

IBM MQ uses the ibmwebspheremq prefix on a label to avoid confusion with certificates for other products. Ensure that you specify the entire certificate label in lower case.

The SSL or TLS server always validates the client certificate if one is sent. If the SSL or TLS client does not send a certificate, authentication fails only if the end of the channel acting as the SSL or TLS server is defined with either the SSLCAUTH parameter set to REQUIRED or an SSLPEER parameter value set. For more information, see Connecting two queue managers using SSL or TLS.

Setting up communications for SSL or TLS on UNIX, Linux or Windows systems

distributed

Secure communications that use the SSL or TLS cryptographic security protocols involve setting up the communication channels and managing the digital certificates that you will use for authentication.

To set up your SSL or TLS installation you must define your channels to use SSL or TLS. You must also create and manage your digital certificates. On UNIX, Linux and Windows systems, you can perform the tests with self–signed certificates.

Self-signed certificates cannot be revoked, which could allow an attacker to spoof an identity after a private key has been compromised. CAs can revoke a compromised certificate, which prevents its further use. CA-signed certificates are therefore safer to use in a production environment, though self-signed certificates are more convenient for a test system.

For full information about creating and managing certificates, see "Working with SSL or TLS on UNIX, Linux and Windows systems" on page 673.

This collection of topics introduces some of the tasks involved in setting up SSL communications, and provides step-by-step guidance on completing those tasks.

You might also want to test SSL oro TLS client authentication, which are an optional part of the protocols. During the SSL or TLS handshake, the SSL or TLS client always obtains and validates a digital certificate from the server. With the IBM MQ implementation, the SSL or TLS server always requests a certificate from the client.

On UNIX, Linux and Windows systems, the SSL or TLS client sends a certificate only if it has one labeled in the correct IBM MQ format:

- For a queue manager, the format is `ibmwebspheremq` followed by the name of your queue manager changed to lower case. For example, for `QM1`, `ibmwebspheremqqm1`
- For an IBM MQ client, `ibmwebspheremq` followed by your logon user ID changed to lower case, for example `ibmwebspheremqmyuserid`.

IBM MQ uses the `ibmwebspheremq` prefix on a label to avoid confusion with certificates for other products. Ensure that you specify the entire certificate label in lower case.

The SSL or TLS server always validates the client certificate if one is sent. If the client does not send a certificate, authentication fails only if the end of the channel acting as the SSL or TLS server is defined with either the SSLCAUTH parameter set to REQUIRED or an SSLPEER parameter value set. For more information, see Connecting two queue managers using SSL or TLS.

Setting up communications for SSL or TLS on z/OS

z/OS

Secure communications that use the SSL or TLS cryptographic security protocols involve setting up the communication channels and managing the digital certificates that you will use for authentication.

To set up your SSL or TLS installation you must define your channels to use SSL or TLS. You must also create and manage your digital certificates. On z/OS you can perform the tests with self-signed certificates, or with personal certificates signed by a local certificate authority (CA).

Self-signed certificates cannot be revoked, which could allow an attacker to spoof an identity after a private key has been compromised. CAs can revoke a compromised certificate, which prevents its further use. CA-signed certificates are therefore safer to use in a production environment, though self-signed certificates are more convenient for a test system.

For full information about creating and managing certificates, see “Working with SSL or TLS on z/OS” on page 703.

This collection of topics introduces some of the tasks involved in setting up SSL or TLS communications, and provides step-by-step guidance on completing those tasks.

You might also want to test SSL or TLS client authentication, which are an optional part of the protocols. During the SSL or TLS handshake, the SSL or TLS client always obtains and validates a digital certificate from the server. With the IBM MQ implementation, the SSL or TLS server always requests a certificate from the client.

On z/OS the SSL or TLS client sends a certificate only if it has one of the following certificates:

- For a shared channel only, a certificate with a label in the format `ibmWebSphereMQ` followed by the name of your queue-sharing group, for example `ibmWebSphereMQQSG1`
- A certificate with a label in the format`ibmWebSphereMQ` followed by the name of your queue manager, for example `ibmWebSphereMQQM1`
- A default certificate (which might be the `ibmWebSphereMQ` certificate).

If the channel is shared, the channel first tries to find a certificate for the queue-sharing group. If it does not find a certificate for a queue-sharing group, it tries to find a certificate for the queue manager.

On z/OS, IBM MQ uses the `ibmWebSphereMQ` prefix on a label to avoid confusion with certificates for other products.

The SSL or TLS server always validates the client certificate if one is sent. If the SSL or TLS client does not send a certificate, authentication fails only if the end of the channel acting as the SSL or TLS server is defined with either the SSLCAUTH parameter set to REQUIRED or an SSLPEER parameter value set. For more information, see Connecting two queue managers using SSL or TLS.

Working with SSL or TLS

These topics give instructions for performing single tasks related to using SSL or TLS with IBM MQ.

Many of them are used as steps in the higher-level tasks described in the following sections:
- "Identifying and authenticating users" on page 715
- "Authorizing access to objects" on page 735
- "Confidentiality of messages" on page 797
- "Data integrity of messages" on page 809
- "Keeping clusters secure" on page 813

Working with SSL or TLS on HP Integrity NonStop Server

Describes the IBM MQ client for HP Integrity NonStop Server OpenSSL security implementation, including security services, components, supported protocol versions, supported CipherSpecs, and unsupported security functionality.

IBM MQ SSL & TLS support provides the following security services for client channels:
- Authentication of the server and, optionally, authentication of the client.
- Encryption and decryption of the data that is flowing across a channel.
- Integrity checks on the data that is flowing across a channel.

The SSL and TLS support supplied with the IBM MQ client for HP Integrity NonStop Server comprises the following components:
- OpenSSL libraries and the **openssl** command.
- IBM MQ password stash command, **amqrsslc**.

The following required components for SSL or TLS client channel operation are not provided with the IBM MQ client for HP Integrity NonStop Server:
- An entropy daemon to provide a source of random data for OpenSSL cryptography.

Supported protocol versions

The IBM MQ client for HP Integrity NonStop Server supports the following protocol versions:
- SSL 3.0
- TLS 1.0
- TLS 1.2

Supported CipherSpecs

The IBM MQ client for HP Integrity NonStop Server supports the following CipherSpecs versions:
- TLS_RSA_WITH_AES_128_CBC_SHA
- TLS_RSA_WITH_AES_256_CBC_SHA
- RC4_SHA_US
- RC4_MD5_US
- TRIPLE_DES_SHA_US
- TLS_RSA_WITH_3DES_EDE_CBC_SHA (deprecated)
- DES_SHA_EXPORT1024
- RC4_56_SHA_EXPORT1024
- RC4_MD5_EXPORT

- RC2_MD5_EXPORT
- DES_SHA_EXPORT
- TLS_RSA_WITH_DES_CBC_SHA
- NULL_SHA
- NULL_MD5
- TLS_RSA_WITH_AES_128_CBC_SHA256
- TLS_RSA_WITH_AES_256_CBC_SHA256
- TLS_RSA_WITH_NULL_SHA256
- TLS_RSA_WITH_AES_128_GCM_SHA256
- TLS_RSA_WITH_AES_256_GCM_SHA384
- ECDHE_ECDSA_AES_128_CBC_SHA256
- ECDHE_ECDSA_AES_256_CBC_SHA384
- ECDHE_RSA_AES_128_CBC_SHA256
- ECDHE_RSA_AES_256_CBC_SHA384
- ECDHE_ECDSA_AES_128_GCM_SHA256
- ECDHE_ECDSA_AES_256_GCM_SHA384
- ECDHE_RSA_AES_128_GCM_SHA256
- ECDHE_RSA_AES_256_GCM_SHA384

Unsupported security functionality

The IBM MQ client for HP Integrity NonStop Server does not currently support:
- PKCS#11 Cryptographic hardware support
- LDAP Certificate Revocation List checking
- OCSP Online Certificate Status Protocol checking
- FIPS 140-2, NSA SUITE B cipher suite controls

Certificate management

Use a set of files to store digital certificate and certificate revocation information.

IBM MQ SSL and TLS support uses a set of files to store digital certificate and certificate revocation information. These files are located in a directory specified either programmatically by way of the KeyRepository field in the MQSCO structure passed on the MQCONNX call, by the *MQSSLKEYR* environment variable, or, in the SSL stanza of the `mqclient.ini` using the SSLKeyRepository attribute.

The MQSCO structure takes precedence over the MQSSLKEYR environment variable which takes precedence over the ini file stanza value.

Important: The key repository location specifies a directory location and not a filename on the HP Integrity NonStop Server platform.

The IBM MQ client for HP Integrity NonStop Server uses the following, case sensitive, named files in the key repository location:
- "Personal certificate store" on page 660
- "Certificate truststore" on page 660
- "Pass phrase stash file" on page 660
- "Certificate revocation list file" on page 661

Personal certificate store:

The personal certificate store file, `cert.pem`.

This file contains the personal certificate and the encrypted private key for the client to use, in PEM format. The existence of this file is optional when you are using SSL or TLS channels that do not require client authentication. Where client authentication is required by the channel, and SSLCAUTH(REQUIRED) is specified on the channel definition, this file must exist and contain both the certificate and encrypted private key.

File permissions must be set on this file to allow read access to the owner of the certificate store.

A correctly formatted `cert.pem` file must contain exactly two sections with the following headers and footers:

```
-----BEGIN PRIVATE KEY-----
Base 64 ASCII encoded private key data here
-----END PRIVATE KEY-----
```

```
-----BEGIN CERTIFICATE-----
Base 64 ASCII encoded certificate data here
-----END CERTIFICATE-----
```

The pass phrase for the encrypted private key is stored in the pass phrase stash file, `Stash.sth`.

Certificate truststore:

The certificate truststore file, `trust.pem`.

This file contains the certificates that are needed to validate the personal certificates that are used by queue managers that the client connects to, in PEM format. The certificate truststore is mandatory for all SSL or TLS client channels.

File permissions must be set to limit write access to this file.

A correctly formatted `trust.pem` file must contain one or more sections with the following headers and footers:

```
-----BEGIN CERTIFICATE-----
Base 64 ASCII encoded certificate data here
-----END CERTIFICATE-----
```

Pass phrase stash file:

The pass phrase stash file, `Stash.sth`.

This file is a binary format private to IBM MQ and contains the encrypted pass phrase for use when you are accessing the private key that is held in the `cert.pem` file. The private key itself is stored in the `cert.pem` certificate store.

This file is created or altered by using the IBM MQ **`amqrsslc`** command-line tool with the **`-s`** parameter. For example, where the directory `/home/alice` contains a `cert.pem` file:

```
amqrsslc -s /home/alice/cert

  Enter password for Keystore /home/alice/cert.pem :
    password

  Stashed the password in file /home/alice/Stash.sth
```

File permissions must be set on this file to allow read access to the owner of the associated personal certificate store.

Certificate revocation list file:

The certificate revocation list file, `crl.pem`.

This file contains the certificate revocation lists (CRLs) that the client uses to validate digital certificates, in PEM format. The existence of this file is optional. If this file is not present, no certificate revocation checks are done when you are validating certificates.

File permissions must be set to limit write access to this file.

A correctly formatted `crl.pem` file must contain one or more sections with the following headers and footers:

```
-----BEGIN X509 CRL-----
Base 64 ASCII encoded CRL data here
-----END X509 CRL-----
```

Working with SSL or TLS on IBM i

IBM i

This collection of topics gives instructions for individual tasks working with the Secure Sockets Layer (SSL) or Transport Layer Security (TLS) in IBM MQ for IBM i.

For IBM i the SSL support is integral to the operating system. Ensure that you have installed the prerequisites listed in Hardware and software requirements on IBM i.

On IBM i, you manage keys and digital certificates with the Digital Certificate Manager (DCM) tool.

Accessing DCM

Follow these instructions to access the DCM interface.

About this task

Perform the following steps in a web browser that supports frames.

Procedure

1. Go to either `http://`*`machine`*`.domain:2001` or `https://`*`machine`*`.domain:2010`, where *machine* is the name of your computer.
2. Type a valid user profile and password when requested to. Ensure that your user profile has *ALLOBJ and *SECADM special authorities to enable you to create new certificate stores. If you do not have the special authorities, you can only manage your personal certificates or view the object signatures for the objects for which you are authorized. If you are authorized to use an object signing application, you can also sign objects from DCM.
3. On the Internet Configurations page, click **Digital Certificate Manager**. The Digital Certificate Manager page is displayed.

Assigning a certificate to a queue manager on IBM i

Use DCM to assign a certificate to a queue manager.

Use traditional IBM i digital certificate management to assign a certificate to a queue manager. This means that you can specify that a queue manager uses the system certificate store, and that the queue manager is registered for use as an application with Digital Certificate Manager. To do this, change the value of the queue manager **SSLKEYR** attribute to `*SYSTEM`.

When the **SSLKEYR** parameter is changed to `*SYSTEM`, IBM MQ registers the queue manager as a server application with a unique application label of QIBM_WEBSPHERE_MQ_QMGRNAME and a label with a description of Qmgrname (WMQ). Note that channel **CERTLABL** attributes are not used if you use the *SYSTEM certificate store. The queue manager then appears as a server application in Digital Certificate Manager, and you can assign to this application any server or client certificate in the system store.

Because the queue manager is registered as an application, advanced features of DCM such as defining CA trust lists can be carried out.

If the **SSLKEYR** parameter is changed to a value other than `*SYSTEM`, IBM MQ deregisters the queue manager as an application with Digital Certificate Manager. If a queue manager is deleted, it is also deregistered from DCM. A user with sufficient *SECADM authority can also manually add or remove applications from DCM.

Setting up a key repository on IBM i

A key repository must be set up at both ends of the connection. The default certificate stores can be used or you can create your own.

An SSL or TLS connection requires a *key repository* at each end of the connection. Each queue manager and IBM MQ MQI client must have access to a key repository. If you want to access the key repository using a file name and password (that is, not using the *SYSTEM option) ensure that the QMQM user profile has the following authorities:

- Execute authority for the directory containing the key repository
- Read authority for the file containing the key repository

See "The SSL or TLS key repository" on page 398 for more information. Note that channel **CERTLABL** attributes are not used if you use the *SYSTEM certificate store.

On IBM i, digital certificates are stored in a certificate store that is managed with DCM. These digital certificates have labels, which associate a certificate with a queue manager or an IBM MQ MQI client. SSL and TLS use the certificates for authentication purposes.

The label is either the value of the **CERTLABL** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client user logon ID appended, all in lowercase. See Digital certificate labels for details.

The queue manager or IBM MQ MQI client certificate store name comprises a path and stem name. The default path is `/QIBM/UserData/ICSS/Cert/Server/` and the default stem name is `Default`. On IBM i, the default certificate store, `/QIBM/UserData/ICSS/Cert/Server/Default.kdb`, is also known as `*SYSTEM`. Optionally, you can define your own path and stem name.

If you define your own path or file name, set the permissions to the file to tightly control access to it.

"Changing the key repository location for a queue manager on IBM i" on page 664 tells you about specifying the certificate store name. You can specify the certificate store name either before or after creating the certificate store.

Note: The operations you can perform with DCM might be limited by the authority of your user profile. For example, you require *ALLOBJ and *SECADM authorities to create a CA certificate.

Creating a certificate store on IBM i:

If you do not want to use the default certificate store, follow this procedure to create your own.

About this task

Create a new certificate store only if you do not want to use the IBM i default certificate store.

To specify that the IBM i system certificate store is to be used, change the value of the queue manager's SSLKEYR attribute to *SYSTEM. This value indicates that the queue manager uses the system certificate store, and the queue manager is registered for use as an application with Digital Certificate Manager (DCM).

Procedure
1. Access the DCM interface, as described in "Accessing DCM" on page 661
2. In the navigation panel, click **Create New Certificate Store**. The Create New Certificate Store page is displayed in the task frame.
3. In the task frame, select **Other System Certificate Store** and click **Continue**. The Create a Certificate in New Certificate Store page is displayed in the task frame.
4. Select **No - Do not create a certificate in the certificate store** and click **Continue**. The Certificate Store Name and Password page is displayed in the task frame.
5. In the **Certificate store path and filename** field, type an IFS path and file name, for example `/QIBM/UserData/mqm/qmgrs/qm1/key.kdb`
6. Type a password in the **Password** field and type it again in the **Confirm Password** field. Click **Continue**. Make a note of the password (which is case sensitive) because you need it when you stash the repository key.
7. To exit from DCM, close your browser window.

What to do next

When you have created the certificate store using DCM, ensure you stash the password, as described in "Stashing the certificate store password on IBM i systems"
Related tasks:
"Importing a certificate into a key repository on IBM i" on page 669
Follow this procedure to import a certificate.

Stashing the certificate store password on IBM i systems:

Stash the certificate store password by using CL commands.

The following instructions apply to stashing the certificate store password on IBM i for a queue manager. Alternatively, for an IBM MQ MQI client, if you are not using the *SYSTEM certificate store (that is, the MQSSLKEYR environment is set to a value other than *SYSTEM), follow the procedure described in the "Stash the certificate store password" on page 672 section of "IBM MQ SSL Client utility (amqrsslc) for IBM i" on page 671.

If you have specified that the *SYSTEM certificate store is to be used (by changing the value of the SSLKEYR attribute of the queue manager to *SYSTEM) you must not follow these steps.

When you have created the certificate store using DCM, use the following commands to stash the password:

```
STRMQM MQMNAME('queue manager name')
CHGMQM MQMNAME('queue manager name') SSLKEYRPWD('password')
```

The password, which is case sensitive, must be entered in single quotation marks exactly as you entered it in step 6 of "Creating a certificate store on IBM i" on page 663.

Note: If you are not using the default system certificate store, and you do not stash the password, attempts to start SSL channels fail because they cannot obtain the password required to access the certificate store.

Locating the key repository for a queue manager on IBM i

Use this procedure to obtain the location of your queue manager's certificate store.

Procedure

1. Display your queue manager's attributes, using the following command:
   ```
   DSPMQM MQMNAME('queue manager name')
   ```
2. Examine the command output for the path and stem name of the certificate store. For example: `/QIBM/UserData/ICSS/Cert/Server/Default`, where `/QIBM/UserData/ICSS/Cert/Server` is the path and `Default` is the stem name.

Changing the key repository location for a queue manager on IBM i

Change the location of your queue manager's certificate store using either CHGMQM or ALTER QMGR.

Procedure

Use either the CHGMQM command or the ALTER QMGR MQSC command to set your queue manager's key repository attribute.

1. Using CHGMQM: `CHGMQM MQMNAME('qm1') SSLKEYR('/QIBM/UserData/ICSS/Cert/Server/MyKey')`
2. Using ALTER QMGR: `ALTER QMGR SSLKEYR('/QIBM/UserData/ICSS/Cert/Server/MyKey')`

In either case, the certificate store has the fully qualified file name: `/QIBM/UserData/ICSS/Cert/Server/MyKey.kdb`

What to do next

When you change the location of a queue manager's certificate store, certificates are not transferred from the old location. If the CA certificates preinstalled when you create the certificate store are insufficient, you must populate the new certificate store with certificates, as described in "Importing a certificate into a key repository on IBM i" on page 669. You must also stash the password for the new location, as described in "Stashing the certificate store password on IBM i systems" on page 663.

Creating a certificate authority and certificate for testing on IBM i

Use this procedure to create a local CA certificate to sign certificate requests, and to create and install the CA certificate.

Before you begin

The instructions in this topic assume that a local certificate authority (CA) does not exist. If a local CA does exist, go to "Requesting a server certificate on IBM i" on page 666.

About this task

The CA certificates that are provided when you install SSL are signed by the issuing CA. On IBM i, you can generate a local certificate authority that can sign server certificates for testing SSL communications on your system. Follow these steps in a Web browser to create a local CA certificate:

Procedure

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the navigation panel, click **Create a Certificate Authority**. The Create a Certificate Authority page is displayed in the task frame.
3. Type a password in the **Certificate store password** field and type it again in the **Confirm password** field.
4. Type a name in the **Certificate Authority (CA) name** field, for example `SSL Test Certificate Authority`.
5. Type appropriate values in the **Common Name** and **Organization** fields, and select a country. For the remaining optional fields, type the values you require.
6. Type a validity period for the local CA in the **Validity period** field. The default value is 1095 days.
7. Click **Continue**. The CA is created, and DCM creates a certificate store and a CA certificate for your local CA.
8. Click **Install certificate**. The download manager dialog box is displayed.
9. Type the full path name for the temporary file in which you want to store the CA certificate and click **Save**.
10. When download is complete, click **Open**. The Certificate window is displayed.
11. Click **Install certificate**. The Certificate Import wizard is displayed.
12. Click **Next**.
13. Select **Automatically select the certificate store based on the type of certificate** and click **Next**.
14. Click **Finish**. A confirmation window is displayed.
15. Click **OK**.
16. In the Certificate window, click **OK**.
17. Click **Continue**. The Certificate Authority Policy page is displayed in the task frame.
18. In the **Allow creation of user certificates** field, select **Yes**.
19. In the **Validity period** field, type the validity period of certificates that are issued by your local CA. The default value is 365 days.
20. Click **Continue**. The Create a Certificate in New Certificate Store page is displayed in the task frame.
21. Check that none of the applications are selected.
22. Click **Continue** to complete the setup of the local CA.

Requesting a server certificate on IBM i

Digital certificates protect against impersonation, certifying that a public key belongs to a specified entity. A new server certificate can be requested from a certificate authority using the Digital Certificate Manager (DCM).

About this task

Perform the following steps in a Web browser:

Procedure

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the navigation panel, click **Select a Certificate Store**. The Select a Certificate Store page is displayed in the task frame.
3. Select the certificate store you want to use and click **Continue**.
4. Optional: If you selected ***SYSTEM** in step 3, enter the system store password and click **Continue**.
5. Optional: If you selected **Other System Certificate Store** in step 3, in the **Certificate store path and filename** field, type the IFS path and file name you set when you created your certificate store. Also type a password in the **Certificate Store Password** field. Then click **Continue**
6. In the navigation panel, click **Create Certificate**.
7. In the task frame, select the **Server or client certificate** radio button and click **Continue**. The Select a Certificate Authority (CA) page is displayed in the task frame.
8. If you have a local CA on your workstation you choose either the local CA or a commercial CA to sign the certificate. Select the radio button for the CA you want and click **Continue**. The Create a Certificate page is displayed in the task frame.
9. Optional: For a queue manager, in the **Certificate label** field, enter the certificate label. The label is either the value of the **`CERTLABL`** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager appended, all in lowercase. See Digital certificate labels for details. For example, for queue manager QM1, type `ibmwebspheremqqm1` to use the default value.
10. Optional: For an IBM MQ MQI client, in the **Certificate label** field, type `ibmwebspheremq` followed by your logon user ID folded to lowercase. For example, type `ibmwebspheremqmyuserID`
11. Type appropriate values in the **Common Name** and **Organization** fields, and select a country. For the remaining optional fields, type the values you require.

Results

If you selected a commercial CA to sign your certificate, DCM creates a certificate request in PEM (Privacy-Enhanced Mail) format. Forward the request to your chosen CA.

If you selected the local CA to sign your certificate, DCM informs you that the certificate has been created in the certificate store and can be used.

Requesting a server certificate on IBM i for IBM Key Manager

Follow this procedure to create a certificate signed by your local certificate authority (CA), or to apply for a server certificate signed by a commercial CA for import into the IBM Key Management (iKeyman) utility.

About this task

A user certificate must be used when the Digital Certificate Manager (DCM) serves as the certificate manager for IBM MQ on multiple platforms. For personal certificates distributed to other platforms and for import into the iKeyman utility, perform the following steps in a Web browser:

Procedure

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the navigation pane, click **Create Certificate**. The Create Certificate page is displayed in the task frame.
3. On the Create Certificate panel, select the **User certificate** radio button and click **Continue**. The Create User Certificate page is displayed.
4. On the Create User Certificate panel, complete the required fields under Certificate Information for **Organization name**, **State** or **province**, **Country** or **region**. Optionally, put values in the **Organization unit** and **Locality** or **city** fields. Click **Continue**. The **Common name** is automatically set to the user ID with which you are logged on to the iSeries system.
5. On the next Create User Certificate panel, click **Install certificate** and click **Continue**. A message is displayed stating, `Your personal certificate has been installed. You should keep a backup copy of this certificate.`
6. Click **OK**.
7. Depending on the internet browser you used to access DCM, do the following steps:
   a. For Internet Explorer choose: **Tools>Internet Options>Content tab>Certificates button>Personal tab>**. Select the certificate and click **Export**.
   b. For Mozilla Firefox choose: **Tools>Options>Advanced>Encryption tab>View Certificates button>Your Certificates tab>**. Select the certificate and click **Backup**. Select the path and filename and click **OK**.
8. Transfer the exported certificate to the remote system using FTP in binary format.
9. Add the exported certificate from step 7 to the iKeyman utility in the key database.
   a. If the certificate was saved using Internet Explorer, use the instructions described in Importing from a Microsoft `.pfx` file.
   b. If the certificate was saved using Mozilla Firefox, use the instructions described in Importing a personal certificate into a key repository.

   During the import, ensure that the label name of the personal certificate and the signer certificate are changed to what IBM MQ is expecting. The label must be either the value of the IBM MQ **`CERTLABL`** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager appended, all in lowercase. See Digital certificate labels for details.

Adding server certificates to a key repository on IBM i

Follow this procedure to add a requested certificate to the key repository.

About this task

After the CA sends you a new server certificate, you add it to the certificate store from which you generated the request. If the CA sends the certificate as part of an email message, copy the certificate into a separate file.

Note:

- You do not need to perform this procedure if the server certificate is signed by your local CA.
- Before you import a server certificate in PKCS #12 format into DCM, you must first import the corresponding CA certificate.

Use the following procedure to receive a server certificate into the queue manager certificate store:

Procedure

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the **Manage Certificates** task category in the navigation panel, click **Import Certificate**. The Import Certificate page displays in the task frame.
3. Select the radio button for your certificate type and click **Continue**. Either the Import Server or Client Certificate page or the Import Certificate Authority (CA) Certificate page displays in the task frame.
4. In the **Import File** field, type the file name of the certificate you want to import and click **Continue**. DCM automatically determines the format of the file.
5. If the certificate is a **Server or client** certificate, type the password in the task frame and click **Continue**. DCM informs you that the certificate has been imported.

Exporting a certificate from a key repository on IBM i

Exporting a certificate exports both the public and private key. This action should be taken with extreme caution, since passing on a private key would completely compromise your security.

Before you begin

When you share a user's certificate with another user, you exchange public keys. This process is described in **Task 5. Sharing Certificates** in the Quick Start Guide for IBM MQ AMS on UNIX platforms . When you export a certificate as described here, you export both the public and private key. This action should be taken with extreme caution, since passing on a private key would completely compromise your security.

About this task

Perform the following steps on the computer from which you want to export the certificate:

Procedure

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the navigation panel, click **Select a Certificate Store**. The Select a Certificate Store page is displayed in the task frame.
3. Select the certificate store you want to use and click **Continue**.
4. Optional: If you selected ***SYSTEM** in step 3, enter the system store password and click **Continue**.
5. Optional: If you selected **Other System Certificate Store** in step 3, in the **Certificate store path and filename** field, type the IFS path and file name you set when you created your certificate store and type a password in the **Certificate Store Password** field. Then click **Continue**

6. In the **Manage Certificates** task category in the navigation panel, click **Export Certificate**. The Export a Certificate page is displayed in the task frame.
7. Select the radio button for your certificate type and click **Continue**. Either the Export Server or Client Certificate page or the Export Certificate Authority (CA) Certificate page is displayed in the task frame.
8. Select the certificate you want to export.
9. Select the radio button to specify whether you want to export the certificate to a file or directly into another certificate store.
10. If you selected to export a server or client certificate to a file, provide the following information:
    - The path and file name of the location where you want to store the exported certificate.
    - For a personal certificate, the password that is used to encrypt the exported certificate and the target release. For CA certificates, you do not need to specify the password.
11. If you selected to export a certificate directly into another certificate store, specify the target certificate store and its password.
12. Click **Continue**.

Importing a certificate into a key repository on IBM i

Follow this procedure to import a certificate.

Before you begin

Before you import a personal certificate in PKCS #12 format into DCM, you must first import the corresponding CA certificate.

About this task

Perform these steps on the machine to which you want to import the certificate.

Procedure

1. Access the DCM interface, as described in “Accessing DCM” on page 661.
2. In the navigation panel, click **Select a Certificate Store**. The Select a Certificate Store page is displayed in the task frame.
3. Select the certificate store you want to use and click **Continue**.
4. Optional: If you selected ***SYSTEM** in step 3, enter the system store password and click **Continue**.
5. Optional: If you selected **Other System Certificate Store** in step 3, in the **Certificate store path and filename** field, type the IFS path and file name you set when you created your certificate store and type a password in the **Certificate Store Password** field. Then click **Continue**
6. In the **Manage Certificates** task category in the navigation panel, click **Import Certificate**. The Import Certificate page is displayed in the task frame.
7. Select the radio button for your certificate type and click **Continue**. Either the Import Server or Client Certificate page or the Import Certificate Authority (CA) Certificate page is displayed in the task frame.
8. In the **Import File** field, type the file name of the certificate you want to import and click **Continue**. DCM automatically determines the format of the file.
9. If the certificate is a **Server or client** certificate, type the password in the task frame and click **Continue**. DCM informs you that the certificate has been imported.

Removing certificates in IBM i

Use this procedure to remove personal certificates.

Procedure

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the navigation panel, click **Select a Certificate Store**. The Select a Certificate Store page is displayed in the task frame.
3. Select the **Other System Certificate Store** check box and click **Continue**. The Certificate Store and Password page is displayed.
4. In the **Certificate store path and filename** field, type the IFS path and file name you set when you created the certificate store.
5. Type a password in the **Certificate Store Password** field. Click **Continue**. The Current Certificate Store page is displayed in the task frame.
6. In the **Manage Certificates** task category in the navigation panel, click **Delete Certificate**. The Confirm Delete Certificate page is displayed in the task frame.
7. Select the certificate you want to delete. Click **Delete**.
8. Click **Yes** to confirm that you want to delete the certificate. Otherwise, click **No**. DCM informs you if it has deleted the certificate.

Using the *SYSTEM certificate store for one-way authentication on IBM i

Follow these instructions to set up one-way authentication.

Before you begin

- Create a queue manager, channels, and transmission queues.
- Create a server or client certificate on the server queue manager.
- Transfer the CA certificate to the client queue manager and imported it into the key repository.
- Start a listener on the server and client queue managers.

About this task

To use one-way authentication, using a computer running IBM i as the SSL server, set the SSL Key Repository (SSLKEYR) parameter to *SYSTEM. This setting registers the IBM MQ queue manager as an application. You can then assign a certificate to the queue manager to enable one-way authentication.

You can also use private keystores to implement one-way authentication by creating a dummy certificate for the client queue manager in the key repository.

Procedure

1. Perform the following steps on the server and client queue managers:
   a. Alter the queue manager to set the SSLKEYR parameter by issuing the command `CHGMQM MQMNAME(SSL) SSLKEYR(*SYSTEM)`.
   b. Stash the password for the default key repository by issuing the command `CHGMQM MQMNAME(SSL) SSLKEYRPWD('xxxxxxx')`. The password must be in single quotation marks.
   c. Alter the channels to have the correct CipherSpec in the SSLCIPHER parameter.
   d. Refresh SSL security by issuing the command `RFRMQMAUT QMNAME(QMGRNAME) TYPE(*SSL)`.
2. Assign the certificate to the server queue manager using DCM, as follows:
   a. Access the DCM interface, as described in "Accessing DCM" on page 661.
   b. In the navigation panel, click **Select a Certificate Store**. The Select a Certificate Store page is displayed in the task frame.
   c. Select the *SYSTEM certificate store and click **Continue**.

d. In the left panel, expand **Manage Applications**.

e. Select the **View Application** definition to check that the queue manager has been registered as an application. `SSL (WMQ)` is listed in the table.

f. Select **Update Certificate Assignment**.

g. Select **Server** and click **Continue**.

h. Select QMGRNAME (WMQ) and click **Update certificate assignment**.

i. Select the certificate and click **Assign New Certificate**. A window opens stating that the certificate has been assigned to the application.

IBM MQ SSL Client utility (amqrsslc) for IBM i

The IBM MQ SSL Client utility (amqrsslc) for IBM i is used by the IBM MQ MQI client on IBM i systems to register or unregister the client user profile, or stash the certificate store password. The utility can only be run by a user with a profile with *ALLOBJ special authority or a member of QMQMADM that has options to create or delete application registrations in the Digital Certificate Manager (DCM).

Syntax diagram

```
►►—amqrsslc——┬—-s—PathOfKeyDatabase—————————┬——————————————————————————————————►◄
             │     ┌—current user—┐          │
             ├—-r——┤              ├——————————┤
             │     └—UserProfile——┘          │
             │     ┌—current user—┐          │
             └—-u——┤              ├——————————┘
                   └—UserProfile——┘
```

Register the client user profile

If the IBM MQ MQI client is using the *SYSTEM certificate store, you must register the client user profile (logon user) for use as an application with Digital Certificate Manager (DCM).

If you want to register the client user profile, run the **amqrsslc** program with the `-r` option with *UserProfile*. The user profile used when calling **amqrsslc** must have *USE authority. Providing *UserProfile* with the `-r` option registers the *UserProfile* as a server application with a unique application label of QIBM_WEBSPHERE_MQ_< *UserProfile* > and a label with a description of < *UserProfile* > (WMQ). This server application then is displayed in the DCM, and you can assign to this application any server or client certificate in the system store.

Note: If a user profile is not specified with `-r` option, then the user profile of the user running the **amqrsslc** tool is registered.
The following code uses **amqrsslc** to register a user profile. In the first example, the specified user profile is registered; in the second it is the profile of the logged in user:

```
CALL PGM(QMQM/AMQRSSLC) PARM('-r' UserProfile)
CALL PGM(QMQM/AMQRSSLC) PARM('-r')
```

Unregister the client user profile

To unregister the client profile, run the **amqrsslc** program with the `-u` option with *UserProfile*. The user profile used when calling **amqrsslc** must have *USE authority. Providing the *UserProfile* with the `-u` option unregisters *UserProfile* with label QIBM_WEBSPHERE_MQ_< *UserProfile* > from the DCM.

Note: If a user profile is not specified with `-u` option, then the user profile of the user running the **amqrsslc** tool is unregistered.

The following code uses **amqrsslc** to unregister a user profile. In the first example, the specified user profile is unregistered; in the second it is the profile of the logged in user:

```
CALL PGM(QMQM/AMQRSSLC) PARM('-u' UserProfile)
CALL PGM(QMQM/AMQRSSLC) PARM('-u')
```

Stash the certificate store password

If the IBM MQ MQI client is not using the *SYSTEM certificate store and using another certificate store (that is, MQSSLKEYR is set to value other than *SYSTEM), then the password of the key database must be stashed. Use `-s` option for stashing the password of key database.

In the following code, the fully qualified file name of the certificate store is `/Path/Of/KeyDatabase/MyKey.kdb`:

```
CALL PGM(QMQM/AMQRSSLC) PARM('-s' '/Path/Of/KeyDatabase/MyKey')
```

Running this code results in a request for the password of this key database. This password is stashed in a file with the same name as key database with a .sth extension. This file is stored on the same path as the key database. The code example generates a stash file of `/Path/Of/KeyDatabase/MyKey.sth`. QMQM is the user owner and QMQMADM the group owner for this file. QMQM and QMQMADM have read, write permission, and other profiles have only read permission.

When changes to certificates or the certificate store become effective on IBM i

When you change the certificates in a certificate store, or the location of the certificate store, the changes take effect depending on the type of channel and how the channel is running.

Changes to the certificates in the certificate store and to the key repository attribute become effective in the following situations:

- When a new outbound single channel process first runs an SSL channel.
- When a new inbound TCP/IP single channel process first receives a request to start an SSL channel.
- When the MQSC command REFRESH SECURITY TYPE(SSL) is issued to refresh the IBM MQ SSL environment.
- For client application processes, when the last SSL connection in the process is closed. The next SSL connection picks up the certificate changes.
- For channels that run as threads of a process pooling process (amqrmppa), when the process pooling process is started or restarted and first runs an SSL channel. If the process pooling process has already run an SSL channel, and you want the change to become effective immediately, run the MQSC command REFRESH SECURITY TYPE(SSL).
- For channels that run as threads of the channel initiator, when the channel initiator is started or restarted and first runs an SSL channel. If the channel initiator process has already run an SSL channel, and you want the change to become effective immediately, run the MQSC command REFRESH SECURITY TYPE(SSL).
- For channels that run as threads of a TCP/IP listener, when the listener is started or restarted and first receives a request to start an SSL channel. If the listener has already run an SSL channel, and you want the change to become effective immediately, run the MQSC command REFRESH SECURITY TYPE(SSL).

Configuring cryptographic hardware on IBM i

Use this procedure to configure the 4758 PCI Cryptographic Coprocessor on IBM i

Before you begin

Ensure your user profile has *ALLOBJ and *SECADM special authorities to enable you to configure the coprocessor hardware.

Procedure

1. Go to either `http://machine.domain:2001` or `https://machine.domain:2010`, where *machine* is the name of your computer. A dialog box is displayed, requesting a user name and a password.
2. Type a valid IBM i user profile and password.
3. On the AS/400 Tasks page, click **4758 PCI Cryptographic Coprocessor**.

What to do next

For more information about configuring the 4758 PCI Cryptographic Coprocessor, refer to the *IBM i product documentation* at IBM System i and IBM i product documentation.

Working with SSL or TLS on UNIX, Linux and Windows systems

On UNIX, Linux and Windows systems, Secure Sockets Layer (SSL) or Transport Layer Security (TLS) support is installed with IBM MQ.

For more detailed information about certificate validation policies, see Certificate validation and trust policy design.

Using runmqckm, runmqakm, and strmqikm to manage digital certificates

On UNIX, Linux and Windows systems, manage keys and digital certificates with the **strmqikm** (iKeyman) GUI, or from the command line using **runmqckm** (iKeycmd) or **runmqakm** (GSKCapiCmd).

- For **UNIX and Linux** systems:
  - Use the **strmqikm** (iKeyman) command to start the iKeyman GUI.
  - Use the **runmqckm** (iKeycmd) command to perform tasks with the iKeycmd command line interface.
  - Use the **runmqakm** (GSKCapiCmd) command to perform tasks with the runmqakm command line interface. The command syntax for **runmqakm** is the same as the syntax for **runmqckm**.

    If you need to manage SSL certificates in a way that is FIPS compliant, use the **runmqakm** command instead of the **runmqckm** or **strmqikm** commands.

  See Managing keys and certificates for a full description of the command line interfaces for the **runmqckm** and **runmqakm** commands.

  If you are using certificates or keys stored on PKCS #11 cryptographic hardware, note that iKeycmd and iKeyman are 64-bit programs. External modules required for PKCS #11 support will be loaded into a 64-bit process, therefore you must have a 64-bit PKCS #11 library installed for the administration of cryptographic hardware. The Windows and Linux x86 32-bit platforms are the only exceptions, as the iKeyman and iKeycmd programs are 32-bit on those platforms.

  See GSKit: PKCS#11 and JRE addressing mode for further information.

  Before you run the **strmqikm** command to start the iKeyman GUI, ensure you are working on a machine that is able to run the X Window System and that you do the following:
  - Set the DISPLAY environment variable, for example:

    ```
    export DISPLAY=mypc:0
    ```
  - Ensure that your PATH environment variable contains **/usr/bin** and **/bin**. This is also required for the **runmqckm** and **runmqakm** commands. For example:

    ```
    export PATH=$PATH:/usr/bin:/bin
    ```

- For **Windows** systems:
  - Use the **`strmqikm`** command to start the iKeyman GUI.
  - Use the **`runmqckm`** command to perform tasks with the iKeycmd command line interface.

    If you need to manage SSL certificates in a way that is FIPS compliant, use the **`runmqakm`** command instead of the **`runmqckm`** or **`strmqikm`** commands.

To request SSL tracing on UNIX, Linux or Windows systems, see strmqtrc.

runmqckm, and runmqakm commands

Setting up a key repository on UNIX, Linux, and Windows systems

You can set up a key repository by the using **`strmqikm`** (iKeyman) GUI, or from the command line using **`runmqckm`** (iKeycmd) or **`runmqakm`** (GSKCapiCmd) commands.

About this task

An SSL or TLS connection requires a *key repository* at each end of the connection. Each IBM MQ queue manager and IBM MQ MQI client must have access to a key repository. For more information, see "The SSL or TLS key repository" on page 398.

On UNIX, Linux, and Windows systems, digital certificates are stored in a key database file that is managed by using the **`iKeyman`** user interface, or by using the **`iKeycmd`** or **`runmqakm`** commands. These digital certificates have labels. A specific label associates a personal certificate with a queue manager or IBM MQ MQI client. SSL and TLS use that certificate for authentication purposes. On UNIX, Linux, and Windows systems, IBM MQ uses either the value of the **`CERTLABL`** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client user logon ID appended, all in lowercase. See Digital certificate labels for details.

The key database file name comprises a path and stem name:

- On UNIX and Linux systems, the default path for a queue manager (set when you created the queue manager) is `/var/mqm/qmgrs/<queue_manager_name>/ssl`.

  On Windows systems, the default path is `*MQ_INSTALLATION_PATH*\Qmgrs\*queue_manager_name*\ssl`, where `*MQ_INSTALLATION_PATH*` is the directory in which IBM MQ is installed. For example, `C:\Program Files\IBM\WebSphere MQ\Qmgrs\QM1\ssl`.

  The default stem name is `key`. Optionally, you can choose your own path and stem name, but the extension must be `.kdb`.

  If you choose your own path or file name, set the permissions to the file to tightly control access to it.
- For an IBM MQ client, there is no default path or stem name. Tightly control access to this file. The extension must be `.kdb`.

Do not create key repositories on a file system that does not support file level locks, for example NFS version 2 on Linux systems.

See "Changing the key repository location for a queue manager on UNIX, Linux or Windows systems" on page 679 for information about checking and specifying the key database file name. You can specify the key database file name either before or after creating the key database file.

The user ID from which you run the **`iKeyman`** or **`iKeycmd`** commands must have write permission for the directory in which the key database file is created or updated. For a queue manager using the default `ssl` directory, the user ID from which you run **`iKeyman`** or **`iKeycmd`** must be a member of the mqm group. For an IBM MQ MQI client, if you run **`iKeyman`** or **`iKeycmd`** from a user ID different from that under which the client runs, you must alter the file permissions to enable the IBM MQ MQI client to access the key database file at run time. For more information, see "Accessing and securing your key database files on Windows" on page 676 or "Accessing and securing your key database files on UNIX and Linux systems" on page 677.

In **iKeyman** or **iKeycmd** Version 7.0, new key databases are automatically populated with a set of pre-defined certificate authority (CA) certificates. In **iKeyman** or **iKeycmd** Version 8.0, key databases are not automatically populated, making the initial setup more secure because you include only the CA certificates that you want, in your key database file.

Note: Because of this change in behavior for GSKit Version 8.0 that results in CA certificates no longer being automatically added to the repository, you must manually add your preferred CA certificates. This change of behavior provides you with more granular control over the CA certificates used. See "Adding default CA certificates into an empty key repository, on UNIX, Linux or Windows systems with GSKit Version 8.0" on page 677.

Procedure

Note: If you must manage SSL or TLS certificates in a way that is FIPS-compliant, use the **runmqakm** command. The **iKeyman** user interface does not provide a FIPS-compliant option.

- To create a key database by using the iKeyman user interface, complete the following steps:
  1. On UNIX and Linux systems, log in as the root user. On Windows systems, log in as Administrator or as a member of the MQM group.
  2. Start the iKeyman user interface by running the **strmqikm** command.
  3. From the **Key Database File** menu, click **New**. The New window opens.
  4. Click **Key database type** and select **CMS** (Certificate Management System).
  5. In the **File Name** field, type a file name. This field already contains the text `key.kdb`. If your stem name is `key`, leave this field unchanged. If you specified a different stem name, replace `key` with your stem name. However, you must not change the `.kdb` extension.
  6. In the **Location** field, type the path. For example:
     - For a queue manager: `/var/mqm/qmgrs/QM1/ssl` (on UNIX and Linux systems) or `C:\ProgramData\IBM\MQ\qmgrs\QM1\ssl` (on Windows systems).

       The path must match the value of the **SSLKeyRepository** attribute of the queue manager.
     - For an IBM MQ client: `/var/mqm/ssl` (on UNIX and Linux systems) or `C:\mqm\ssl` (on Windows systems).
  7. Click **OK**. The Password Prompt window opens.
  8. Type a password in the **Password** field, and type it again in the **Confirm Password** field.
  9. Select the **Stash the password to a file** check box.

     Note: If you do not stash the password, attempts to start SSL or TLS channels fail because they cannot obtain the password required to access the key database file.
  10. Click **OK**. The Personal Certificates window opens.
  11. Set the access permissions as described in "Accessing and securing your key database files on Windows" on page 676 or "Accessing and securing your key database files on UNIX and Linux systems" on page 677.
- To create a key database by using the command line, use either of the following commands:
  - On UNIX, Linux, and Windows systems:
    ```
    runmqckm -keydb -create -db filename -pw password -type cms -stash
    ```
  - Using runmqakm:
    ```
    runmqakm -keydb -create -db filename -pw password -type cms
    -stash -fips -strong
    ```

  where:

-db ***filename***
: Specifies the fully qualified file name of a CMS key database, and must have a file extension of `.kdb`.

-pw ***password***
: Specifies the password for the CMS key database.

-type ***cms***
: Specifies the type of database. (For IBM MQ, it must be `cms`.)

-stash
: Saves the key database password to a file.

-fips
: Specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that are FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

-strong
: Checks that the password entered satisfies the minimum requirements for password strength. The minimum requirements for a password are as follows:
  - The password must be a minimum length of 14 characters.
  - The password must contain a minimum of one lowercase character, one uppercase character, and one digit or special character. Special characters include the asterisk (*), the dollar sign ($), the number sign (#), and the percent sign (%). A space is classified as a special character.
  - Each character can occur a maximum of three times in a password.
  - A maximum of two consecutive characters in the password can be identical.
  - All characters are in the standard ASCII printable character set, within the range 0x20 - 0x7E.

Accessing and securing your key database files on Windows:

The key database files might not have appropriate access permissions. You must set appropriate access to these files.

Set access control to the files *key*.kdb, *key*.sth, *key*.crl, and *key*.rdb, where *key* is the stem name of your key database, to grant authority to a restricted set of users.

Consider granting access as follows:

full authority
: BUILTIN\Administrators, NT AUTHORITY\SYSTEM, and the user who created the database files.

read authority
: For a queue manager, the local mqm group only. This assumes that the MCA is running under a user ID in the mqm group.

  For a client, the user ID under which the client process is running.

Accessing and securing your key database files on UNIX and Linux systems:

The key database files might not have appropriate access permissions. You must set appropriate access to these files.

For a queue manager, set permissions on the key database files so that queue manager and channel processes can read them when necessary, but other users cannot read or modify them. Normally, the mqm user needs read permissions. If you have created the key database file by logging in as the mqm user, then the permissions are probably sufficient; if you were not the mqm user, but another user in the mqm group, you probably need to grant read permissions to other users in the mqm group.

Similarly for a client, set permissions on the key database files so that client application processes can read them when necessary, but other users cannot read or modify them. Normally, the user under which the client process runs needs read permissions. If you have created the key database file by logging in as that user, then the permissions are probably sufficient; if you were not the client process user, but another user in that group, you probably need to grant read permissions to other users in the group.

Set the permissions on the files `*key*.kdb`, `*key*.sth`, `*key*.crl`, and `*key*.rdb`, where *key* is the stem name of your key database, to read and write for the file owner, and to read for the mqm or client user group (-rw-r-----).

Adding default CA certificates into an empty key repository, on UNIX, Linux or Windows systems with GSKit Version 8.0:

Follow this procedure to add one or more of the default CA certificates to an empty key repository with GSKit version 8.

In GSKit Version 7.0, the behavior when creating a new key repository was to automatically add in a set of default CA certificates for commonly-used Certificate Authorities. For GSKit version 8, this behavior has changed so that CA certificates are no longer automatically added to the repository. The user is now required to manually add CA certificates into the key repository.

Using iKeyman

Perform the following steps on the machine on which you want to add the CA certificate:
1. Start the iKeyman GUI using the **`strmqikm`** command (on UNIX, Linux and Windows systems).
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file to which you want to add the certificate, for example `key.kdb`.
6. Click **Open**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file displays in the **File Name** field.
8. In the **Key database content** field, select **Signer Certificates**.
9. Click **Populate**. The Add CA's Certificate window opens.
10. The CA certificates that are available to be added to the repository are displayed in a hierarchical tree structure. Select the top level entry for the organization whose CA certificates you wish to trust to view the complete list of valid CA certificates.
11. Select the CA certificates you wish to trust from the list and click **OK**. The certificates are added to the key repository.

Using the command line

Use the following commands to list, then add CA certificates using iKeycmd:

- Issue the following command to list the default CA certificates along with the organizations which issue them:

  ```
  runmqckm -cert -listsigners
  ```

- Issue the following command to add all of the CA certificates for the organization specified in the *label* field:

  ```
  runmqckm -cert -populate -db filename -pw password -label label
  ```

where:

`-db` *filename*	is the fully qualified path name of the key database.
`-pw` *password*	is the password for the key database.
`-label` *label*	is the label attached to the certificate.

Note: Adding a CA certificate to a key repository results in IBM MQ trusting all personal certificates signed by that CA certificate. Consider carefully which Certificate Authorities you wish to trust and only add the set of CA certificates needed to authenticate your clients and managers. It is not recommended to add the full set of default CA certificates unless this is a definitive requirement for your security policy.

Locating the key repository for a queue manager on UNIX, Linux or Windows systems

Use this procedure to obtain the location of your queue manager's key database file

Procedure

1. Display your queue manager's attributes, using either of the following MQSC commands:

   ```
   DISPLAY QMGR ALL
   DISPLAY QMGR SSLKEYR
   ```

   You can also display your queue manager's attributes using the IBM MQ Explorer or PCF commands.
2. Examine the command output for the path and stem name of the key database file. For example,
   a. on UNIX and Linux systems: `/var/mqm/qmgrs/QM1/ssl/key`, where `/var/mqm/qmgrs/QM1/ssl` is the path and `key` is the stem name
   b. on Windows: *MQ_INSTALLATION_PATH*`\qmgrs\QM1\ssl\key`, where *MQ_INSTALLATION_PATH*`\qmgrs\QM1\ssl` is the path and `key` is the stem name. *MQ_INSTALLATION_PATH* represents the high-level directory in which IBM MQ is installed.

Changing the key repository location for a queue manager on UNIX, Linux or Windows systems

You can change the location of your queue manager's key database file by various means including the MQSC command ALTER QMGR.

You can change the location of your queue manager's key database file by using the MQSC command ALTER QMGR to set your queue manager's key repository attribute. For example, on UNIX and Linux systems:

```
ALTER QMGR SSLKEYR('/var/mqm/qmgrs/QM1/ssl/MyKey')
```

The key database file has the fully qualified file name: `/var/mqm/qmgrs/QM1/ssl/MyKey.kdb`

On Windows:

```
ALTER QMGR SSLKEYR('C:\Program Files\IBM\WebSphere MQ\Qmgrs\QM1\ssl\Mykey')
```

The key database file has the fully qualified file name: `C:\Program Files\IBM\WebSphere MQ\Qmgrs\QM1\ssl\Mykey.kdb`

Attention: Ensure that you do not include the `.kdb` extension in the file name on the SSLKEYR keyword, as the queue manager appends this extension automatically.

You can also alter your queue manager's attributes using the IBM MQ Explorer or PCF commands.

When you change the location of a queue manager's key database file, certificates are not transferred from the old location. If the key database file you are now accessing is a new key database file, you must populate it with the CA and personal certificates you need, as described in "Importing a personal certificate into a key repository on UNIX, Linux or Windows systems" on page 692.

Locating the key repository for an IBM MQ MQI client on UNIX, Linux and Windows systems.

The location of the key repository is given by the MQSSLKEYR variable, or specified in the MQCONNX call.

Examine the MQSSLKEYR environment variable to find the location of the key database file for your IBM MQ MQI client. For example:

```
echo $MQSSLKEYR
```

Also check your application, because the key database file name can also be set in an MQCONNX call, as described in"Specifying the key repository location for an IBM MQ MQI client on UNIX, Linux or Windows systems" on page 680. The value set in an MQCONNX call overrides the value of MQSSLKEYR.

Specifying the key repository location for an IBM MQ MQI client on UNIX, Linux or Windows systems

There is no default key repository for an IBM MQ MQI client. You can specify its location in either of two ways. Ensure that the key database file can be accessed only by intended users or administrators to prevent unauthorized copying to other systems.

You can specify the location of the key database file for your IBM MQ MQI client in two ways:

- Setting the MQSSLKEYR environment variable. For example, on UNIX and Linux systems:

  ```
  export MQSSLKEYR=/var/mqm/ssl/key
  ```

  The key database file has the fully-qualified file name:

  ```
  /var/mqm/ssl/key.kdb
  ```

  On Windows:

  ```
  set MQSSLKEYR=C:\Program Files\IBM\WebSphere MQ\ssl\key
  ```

  The key database file has the fully-qualified file name:

  ```
  C:\Program Files\IBM\WebSphere MQ\ssl\key.kdb
  ```

  Note: The `.kdb` extension is a mandatory part of the file name, but is not included as part of the value of the environment variable.
- Providing the path and stem name of the key database file in the *KeyRepository* field of the MQSCO structure when an application makes an MQCONNX call. For more information about using the MQSCO structure in MQCONNX, see Overview for MQSCO.

When changes to certificates or the certificate store become effective on UNIX, Linux or Windows systems.

When you change the certificates in a certificate store, or the location of the certificate store, the changes take effect depending on the type of channel and how the channel is running.

Changes to the certificates in the key database file and to the key repository attribute become effective in the following situations:

- When a new outbound single channel process first runs an SSL channel.
- When a new inbound TCP/IP single channel process first receives a request to start an SSL channel.
- When the MQSC command REFRESH SECURITY TYPE(SSL) is issued to refresh the Websphere MQ SSL environment.
- For client application processes, when the last SSL connection in the process is closed. The next SSL connection will pick up the certificate changes.
- For channels that run as threads of a process pooling process (amqrmppa), when the process pooling process is started or restarted and first runs an SSL channel. If the process pooling process has already run an SSL channel, and you want the change to become effective immediately, run the MQSC command REFRESH SECURITY TYPE(SSL).
- For channels that run as threads of the channel initiator, when the channel initiator is started or restarted and first runs an SSL channel. If the channel initiator process has already run an SSL channel, and you want the change to become effective immediately, run the MQSC command REFRESH SECURITY TYPE(SSL).
- For channels that run as threads of a TCP/IP listener, when the listener is started or restarted and first receives a request to start an SSL channel. If the listener has already run an SSL channel, and you want the change to become effective immediately, run the MQSC command REFRESH SECURITY TYPE(SSL).

You can also refresh the IBM MQ SSL environment using the IBM MQ Explorer or PCF commands.

Creating a self-signed personal certificate on UNIX, Linux, and Windows systems

You can create a self-signed certificate by using the **strmqikm** (iKeyman) GUI, or from the command line using **runmqckm** (iKeycmd) or **runmqakm** (GSKCapiCmd).

Note: IBM MQ does not support SHA-3 or SHA-5 algorithms. You can use the digital signature algorithm names SHA384WithRSA and SHA512WithRSA because both algorithms are members of the SHA-2 family.

The digital signature algorithm names SHA3WithRSA and SHA5WithRSA are deprecated because they are an abbreviated form of SHA384WithRSA and SHA512WithRSA respectively.

For more information about why you might want to use self-signed certificates, see Using self-signed certificates for mutual authentication of two queue managers.

Not all digital certificates can be used with all CipherSpecs. Ensure that you create a certificate that is compatible with the CipherSpecs you need to use. IBM MQ supports three different types of CipherSpec. For details, see "Interoperability of Elliptic Curve and RSA CipherSpecs" on page 420 in the "Digital certificates and CipherSpec compatibility in IBM MQ" on page 419 topic. To use the Type 1 CipherSpecs (those with names beginning `ECDHE_ECDSA_`) you must use the **runmqakm** command to create the certificate and you must specify an Elliptic Curve ECDSA signature algorithm parameter; for example, **-sig_alg** `EC_ecdsa_with_SHA384`.

Using iKeyman

iKeyman does not provide a FIPS-compliant option. If you need to manage SSL or TLS certificates in a way that is FIPS-compliant, use the **runmqakm** command.

Use the following procedure to obtain a self-signed certificate for your queue manager or IBM MQ MQI client:

1. Start the iKeyman GUI by using the **strmqikm** command .
2. From the **Key Database File** menu, click **Open**. The Open window displays.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file in which you want to save the certificate, for example `key.kdb`.
6. Click **OK**. The Password Prompt window displays.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is displayed in the **File Name** field.
8. From the **Create** menu, click **New Self-Signed Certificate**. The Create New Self-Signed Certificate window is displayed.
9. In the **Key Label** field, enter the certificate label. The label is either the value of the **CERTLABL** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client logon user ID appended, all in lowercase. See Digital certificate labels for details.
10. Type or select a value for any field in the **Distinguished name**, or any of the **Subject alternative name** fields.
11. For the remaining fields, either accept the default values, or type or select new values. For more information about Distinguished Names, see "Distinguished Names" on page 384.
12. Click **OK**. The **Personal Certificates** list shows the label of the self-signed personal certificate you created.

Using the command line

Use the following commands to create a self-signed personal certificate by using **iKeycmd** or **runmqakm**:

- Using **iKeycmd** on UNIX, Linux and Windows systems:

```
runmqckm -cert -create -db filename -pw password -label label
        -dn distinguished_name -size key_size
 -x509version version -expire days
 -sig_alg algorithm
```

Instead of -dn *distinguished_name*, you can use -san_dsname *DNS_names*, -san_emailaddr *email_addresses*, or -san_ipaddr *IP_addresses*.

- Using **runmqakm**:

```
runmqakm -cert -create -db filename -pw password -label label
        -dn distinguished_name -size key_size
 -x509version version -expire days

        -fips -sig_alg algorithm
```

-db *filename*	The fully qualified file name of a CMS key database.
-pw *password*	The password for the CMS key database.
-label *label*	The key label attached to the certificate. The label is either the value of the **CERTLABL** attribute, if it is set, or the default ibmwebspheremq with the name of the queue manager or the IBM MQ MQI client logon user ID appended, all in lowercase. See "Digital certificate labels, understanding the requirements" on page 400 for details.
-dn *distinguished_name*	The X.500 distinguished name enclosed in double quotation marks. At least one attribute is required. You can supply multiple OU or DC attributes. **Note:** The **iKeycmd** and **runmqakm** tools refer to the postal code attribute as POSTALCODE, not PC. Always specify POSTALCODE in the **-dn** parameter when you use these certificate management commands to request certificates with a postal code.
-size *key_size*	The key size. For **iKeycmd**, the value can be 512 or 1024. For runmqakm, the value can be 512, 1024, 2048 or 4096.
-x509version *version*	The version of X.509 certificate to create. The value can be 1, 2, or 3. The default is 3.
-expire *days*	The expiration time in days of the certificate. The default is 365 days for a certificate.
-fips	Specifies that the command is run in FIPS mode. Only the FIPS ICC component is used and this component must be successfully initialized in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.
-sig_alg	For runmqakm, the hashing algorithm used during the creation of a self-signed certificate. This hashing algorithm is used to create the signature associated with the newly created self-signed certificate. The value can be md5, MD5_WITH_RSA, MD5WithRSA, SHA_WITH_DSA, SHA_WITH_RSA, sha1, SHA1WithDSA, SHA1WithECDSA, SHA1WithRSA, sha224, SHA224_WITH_RSA, SHA224WithDSA, SHA224WithECDSA, SHA224WithRSA, sha256, SHA256_WITH_RSA, SHA256WithDSA, SHA256WithECDSA, SHA256WithRSA, SHA2WithRSA, sha384, SHA384_WITH_RSA, SHA384WithECDSA, SHA384WithRSA, sha512, SHA512_WITH_RSA, SHA512WithECDSA, SHA512WithRSA, SHAWithDSA, SHAWithRSA, EC_ecdsa_with_SHA1, EC_ecdsa_with_SHA224, EC_ecdsa_with_SHA256, EC_ecdsa_with_SHA384, or EC_ecdsa_with_SHA512. The default value is SHA1WithRSA.
-sig_alg	For iKeycmd, the asymmetric signature algorithm used for the creation of the entry's key pair. The value can be MD2_WITH_RSA, MD2WithRSA, MD5_WITH_RSA, MD5WithRSA, SHA1WithDSA, SHA1WithRSA, SHA256_WITH_RSA, SHA256WithRSA, SHA2WithRSA, SHA384_WITH_RSA, SHA384WithRSA, SHA512_WITH_RSA, SHA512WithRSA, SHA_WITH_DSA, SHA_WITH_RSA, SHAWithDSA, or SHAWithRSA. The default value is SHA1WithRSA.
-san_dnsname *DNS_names*	A comma- or space-delimited list of DNS names for the entry being created.
-san_emailaddr *email_addresses*	A comma- or space-delimited list of email addresses for the entry being created.
-san_ipaddr *IP_addresses*	A comma- or space-delimited list of IP addresses for the entry being created.

Requesting a personal certificate on UNIX, Linux, and Windows systems

distributed

You can request a personal certificate by using the **strmqikm** (iKeyman) GUI, or from the command line using the **runmqckm** (iKeycmd) or **runmqakm** (GSKCapiCmd) commands. If you need to manage SSL or TLS certificates in a way that is FIPS-compliant, use the **runmqakm** command.

About this task

You can request a personal certificate using the iKeyman GUI, or from the command line, subject to the following considerations:

- IBM MQ does not support SHA-3 or SHA-5 algorithms. You can use the digital signature algorithm names SHA384WithRSA and SHA512WithRSA because both algorithms are members of the SHA-2 family.
- The digital signature algorithm names SHA3WithRSA and SHA5WithRSA are deprecated because they are an abbreviated form of SHA384WithRSA and SHA512WithRSA respectively.
- Not all digital certificates can be used with all CipherSpecs. Ensure that you request a certificate that is compatible with the CipherSpecs you need to use. IBM MQ supports three different types of CipherSpec. For details, see “Interoperability of Elliptic Curve and RSA CipherSpecs” on page 420 in the “Digital certificates and CipherSpec compatibility in IBM MQ” on page 419 topic.
- To use the Type 1 CipherSpecs (with names beginning `ECDHE_ECDSA_`) you must use the **runmqakm** command to request the certificate and you must specify an Elliptic Curve ECDSA signature algorithm parameter; for example, **-sig_alg** `EC_ecdsa_with_SHA384`.
- Only the runmqakm command provides a FIPS-compliant option.
- If you are using cryptographic hardware, see “Requesting a personal certificate for your PKCS #11 hardware” on page 700.

Using the iKeyman user interface:
About this task

iKeyman does not provide a FIPS-compliant option. If you need to manage SSL or TLS certificates in a way that is FIPS-compliant, use the **runmqakm** command.

Procedure

Complete the following steps to apply for a personal certificate, by using the iKeyman user interface:

1. Start the iKeyman user interface by using the **strmqikm** command.
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file from which you want to generate the request; for example, `key.kdb`.
6. Click **Open**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is shown in the **File Name** field.
8. From the **Create** menu, click **New Certificate Request**. The Create New Key and Certificate Request window opens.
9. In the **Key Label** field, enter the certificate label. The label is either the value of the **CERTLABL** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client logon user ID appended, all in lowercase. See Digital certificate labels for details.

10. Type or select a value for any field in the **Distinguished name** field, or any of the **Subject alternative name** fields. For the remaining fields, either accept the default values, or type or select new values. For more information about Distinguished Names, see "Distinguished Names" on page 384.
11. In the **Enter the name of a file in which to store the certificate request** field, either accept the default `certreq.arm`, or type a new value with a full path.
12. Click **OK**. A confirmation window is displayed.
13. Click **OK**. The **Personal Certificate Requests** list shows the label of the new personal certificate request you created. The certificate request is stored in the file you chose in step 11.
14. Request the new personal certificate either by sending the file to a certificate authority (CA), or by copying the file into the request form on the website for the CA.

Using the command line:
Procedure

Request a personal certificate by using either the **runmqckm** (iKeycmd) or **runmqakm** (GSKCapiCmd) command.

- Using **runmqckm**:

  ```
  runmqckm -certreq -create -db filename -pw password -label label
          -dn distinguished_name -size key_size
   -file filename -sig_alg algorithm
  ```

  Instead of `-dn` *distinguished_name*, you can use `-san_dsname` *DNS_names*, `-san_emailaddr` *email_addresses*, or `-san_ipaddr` *IP_addresses*.
- Using **runmqakm**:

  ```
  runmqakm -certreq -create -db filename -pw password -label label
          -dn distinguished_name -size key_size
   -file filename -fips
          -sig_alg algorithm
  ```

where:

-db *filename*
Specifies the fully qualified file name of a CMS key database.

-pw *password*
Specifies the password for the CMS key database.

-label *label*
Specifies the key label attached to the certificate. The label is either the value of the **CERTLABL** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or the IBM MQ MQI client logon user ID appended, all in lowercase. See "Digital certificate labels, understanding the requirements" on page 400 for details.

-dn *distinguished_name*
Specifies the X.500 distinguished name enclosed in double quotation marks. At least one attribute is required. You can supply multiple OU and DC attributes.

Note: The **runmqckm** and **runmqakm** tools refer to the postal code attribute as `POSTALCODE`, not `PC`. Always specify `POSTALCODE` in the **-dn** parameter when you use these certificate management commands to request certificates with a postal code.

-size *key_size*
Specifies the key size. If you are using **runmqckm**, the value can be `512` or `1024`. If you are using **runmqakm**, the value can be `512`, `1024`, or `2048`.

-file *filename*
Specifies the file name for the certificate request.

-fips
Specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that are FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

-sig_alg
For **runmqckm**, specifies the asymmetric signature algorithm used for the creation of the entry's key pair. The value can be MD2_WITH_RSA, MD2WithRSA, MD5_WITH_RSA, MD5WithRSA, SHA1WithDSA, SHA1WithRSA, SHA256_WITH_RSA, SHA256WithRSA, SHA2WithRSA, SHA384_WITH_RSA, SHA384WithRSA, SHA512_WITH_RSA, SHA512WithRSA, SHA_WITH_DSA, SHA_WITH_RSA, SHAWithDSA, or SHAWithRSA. The default value is SHA1WithRSA

-sig_alg
For **runmqakm**, specifies the hashing algorithm used during the creation of a certificate request. This hashing algorithm is used to create the signature associated with the newly created certificate request. The value can be md5, MD5_WITH_RSA, MD5WithRSA, SHA_WITH_DSA, SHA_WITH_RSA, sha1, SHA1WithDSA, SHA1WithECDSA, SHA1WithRSA, sha224, SHA224_WITH_RSA, SHA224WithDSA, SHA224WithECDSA, SHA224WithRSA, sha256, SHA256_WITH_RSA, SHA256WithDSA, SHA256WithECDSA, SHA256WithRSA, SHA2WithRSA, sha384, SHA384_WITH_RSA, SHA384WithECDSA, SHA384WithRSA, sha512, SHA512_WITH_RSA, SHA512WithECDSA, SHA512WithRSA, SHAWithDSA, SHAWithRSA, EC_ecdsa_with_SHA1, EC_ecdsa_with_SHA224, EC_ecdsa_with_SHA256, EC_ecdsa_with_SHA384, or EC_ecdsa_with_SHA512. The default value is SHA1WithRSA.

-san_dnsname ***DNS_names***
Specifies a comma-delimited or space-delimited list of DNS names for the entry being created.

-san_emailaddr ***email_addresses***
Specifies a comma-delimited or space-delimited list of email addresses for the entry being created.

-san_ipaddr ***IP_addresses***
Specifies a comma-delimited or space-delimited list of IP addresses for the entry being created.

What to do next

Submit a certificate request to a CA. See "Receiving personal certificates into a key repository on UNIX, Linux and Windows systems" on page 687 for further information.

Renewing an existing personal certificate on UNIX, Linux, and Windows systems

You can renew a personal certificate by using the **strmqikm** (iKeyman) GUI, or from the command line using the **runmqckm** (iKeycmd) or **runmqakm** (GSKCapiCmd) commands.

About this task

If you have a requirement to use larger key sizes for your personal certificates, you cannot renew an existing certificate. You must replace your existing key by following the steps described in "Requesting a personal certificate on UNIX, Linux, and Windows systems" on page 683 to create a new certificate request that uses the key sizes you require.

A personal certificate has an expiry date, after which the certificate can no longer be used. This task explains how to renew an existing personal certificate before it expires.

Using the iKeyman user interface:
About this task

iKeyman does not provide a FIPS-compliant option. If you need to manage SSL or TLS certificates in a way that is FIPS-compliant, use the **runmqakm** command.

Procedure

Complete the following steps to apply for a personal certificate, by using the iKeyman user interface:

1. Start the iKeyman user interface by using the **strmqikm** command on UNIX, Linux, and Windows systems.
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file from which you want to generate the request; for example, `key.kdb`.
6. Click **Open**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is shown in the **File Name** field.
8. Select **Personal Certificates** from the drop down selection menu, and select the certificate from the list that you want to renew.
9. Click the **Recreate Request...** button. A window opens for you to enter the file name and file location information.
10. In the **file name** field, either accept the default `certreq.arm`, or type a new value, including the full file path.
11. Click **OK**. The certificate request is stored in the file you selected in step 9.
12. Request the new personal certificate either by sending the file to a certificate authority (CA), or by copying the file into the request form on the website for the CA.

Using the command line:
Procedure

Use the following commands to request a personal certificate by using either the **iKeycmd** or **runmqakm** command:

- Using **iKeycmd** on UNIX, Linux, and Windows systems:
```
runmqckm -certreq -recreate -db filename -pw password -label label
 -target filename
```
- Using runmqakm:
```
runmqakm -certreq -recreate -db filename -pw password -label label
-target filename
```

where:

-db *filename*
Specifies the fully qualified file name of a CMS key database.

-pw *password*
Specifies the password for the CMS key database.

-target *filename*
Specifies the file name for the certificate request.

What to do next

Once you have received the signed personal certificate from the certificate authority, you can add it to your key database using the steps described in "Receiving personal certificates into a key repository on UNIX, Linux and Windows systems."

Receiving personal certificates into a key repository on UNIX, Linux and Windows systems

Use this procedure to receive a personal certificate into the key database file. The key repository must be the same repository where you created the certificate request.

After the CA sends you a new personal certificate, you add it to the key database file from which you generated the new certificate request . If the CA sends the certificate as part of an email message, copy the certificate into a separate file.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

Ensure that the certificate file to be imported has write permission for the current user, and then use the following procedure for either a queue manager or an IBM MQ MQI client to receive a personal certificate into the key database file:

1. Start the iKeyman GUI using the **`strmqikm`** command (on Windows UNIX and Linux).
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file to which you want to add the certificate, for example `key.kdb`.
6. Click **Open**, and then click **OK**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is displayed in the **File Name** field. Select the **Personal Certificates** view.
8. Click **Receive**. The Receive Certificate from a File window opens.
9. Type the certificate file name and location for the new personal certificate, or click **Browse** to select the name and location.
10. Click **OK**. If you already have a personal certificate in your key database, a window opens, asking if you want to set the key you are adding as the default key in the database.
11. Click **Yes** or **No**. The Enter a Label window opens.
12. Click **OK**. The **Personal Certificates** field shows the label of the new personal certificate you added.

Using the command line

Use the following commands to add a personal certificate to a key database file using iKeycmd, or runmqakm:

- On UNIX, Linux and Windows, issue the following command:

```
runmqckm -cert -receive -file filename -db filename -pw password
-format ascii
```

where:

`-file` *filename*	is the fully qualified file name of the file containing the personal certificate.
`-db` *filename*	is the fully qualified file name of a CMS key database.
`-pw` *password*	is the password for the CMS key database.
`-format` *ascii*	is the format of the certificate. The value can be `ascii` for Base64-encoded ASCII or `binary` for Binary DER data. The default is `ascii`.
`-fips`	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

If you are using cryptographic hardware, refer to "Importing a personal certificate to your PKCS #11 hardware" on page 702.

Extracting a CA certificate from a key repository

Follow this procedure to extract a CA certificate.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

Perform the following steps on the machine from which you want to extract the CA certificate:

1. Start the iKeyman GUI using the **strmqikm** command..
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file from which you want to extract, for example `key.kdb`.
6. Click **Open**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is displayed in the **File Name** field.
8. In the **Key database content** field, select **Signer Certificates** and select the certificate you want to extract.
9. Click **Extract**. The Extract a Certificate to a File window opens.
10. Select the **Data type** of the certificate, for example **Base64-encoded ASCII data** for a file with the `.arm` extension.
11. Type the certificate file name and location where you want to store the certificate, or click **Browse** to select the name and location.
12. Click **OK**. The certificate is written to the file you specified.

Using the command line

Use the following commands to extract a CA certificate using iKeycmd :

- On UNIX, Linux and Windows:

```
runmqckm -cert -extract -db filename -pw password -label label -target filename
        -format ascii
```

where:

`-db` *filename*	is the fully qualified path name of a CMS key database.
`-pw` *password*	is the password for the CMS key database.
`-label` *label*	is the label attached to the certificate.
`-target` *filename*	is the name of the destination file.
`-format` *ascii*	is the format of the certificate. The value can be `ascii` for Base64-encoded ASCII or `binary` for Binary DER data. The default is `ascii`.
`-fips`	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

Extracting the public part of a self-signed certificate from a key repository on UNIX, Linux and Windows systems

Follow this procedure to extract the public part of a self-signed certificate.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

Perform the following steps on the machine from which you want to extract the public part of a self-signed certificate:

1. Start the iKeyman GUI using the **strmqikm** command (on UNIX, Linux and Windows).
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file from which you want to extract the certificate, for example `key.kdb`.
6. Click **OK**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is displayed in the **File Name** field.
8. In the **Key database content** field, select **Personal Certificates** and select the certificate.
9. Click **Extract certificate**. The Extract a Certificate to a File window opens.
10. Select the **Data type** of the certificate, for example **Base64-encoded ASCII data** for a file with the `.arm` extension.
11. Type the certificate file name and location where you want to store the certificate, or click **Browse** to select the name and location.
12. Click **OK**. The certificate is written to the file you specified. Note that when you extract (rather than export) a certificate, only the public part of the certificate is included, so a password is not required.

Using the command line

Use the following commands to extract the public part of a self-signed certificate using iKeycmd or runmqakm:

- On UNIX, Linux and Windows:
  ```
  runmqckm -cert -extract -db filename -pw password -label label -target filename
          -format ascii
  ```
- Using runmqakm:
  ```
  runmqakm -cert -extract -db filename -pw password -label label
             -target filename -format ascii -fips
  ```

where:

`-db` *filename*	is the fully qualified path name of a CMS key database.
`-pw` *password*	is the password for the CMS key database.
`-label` *label*	is the label attached to the certificate.
`-target` *filename*	is the name of the destination file.
`-format` *ascii*	is the format of the certificate. The value can be `ascii` for Base64-encoded ASCII or `binary` for Binary DER data. The default is `ascii`.
`-fips`	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

Adding a CA certificate (or the public part of a self-signed certificate) into a key repository, on UNIX, Linux or Windows systems

Follow this procedure to add a CA certificate or the public part of a self-signed certificate to the key repository.

If the certificate that you want to add is in a certificate chain, you must also add all the certificates that are above it in the chain. You must add the certificates in strictly descending order starting from the root, followed by the CA certificate immediately below it in the chain, and so on.

Where the following instructions refer to a CA certificate, they also apply to the public part of a self-signed certificate.

Note: You must ensure that the certificate is in ASCII (UTF-8) or binary (DER) encoding, because IBM Global Secure Toolkit (GSKit) does not support certificates with other types of encoding.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

Perform the following steps on the machine on which you want to add the CA certificate:

1. Start the iKeyman GUI using the **strmqikm** command (on UNIX, Linux and Windows systems).
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file to which you want to add the certificate, for example `key.kdb`.
6. Click **OK**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file displays in the **File Name** field.
8. In the **Key database content** field, select **Signer Certificates**.
9. Click **Add**. The Add CA's Certificate from a File window opens.
10. Type the certificate file name and location where the certificate is stored, or click **Browse** to select the name and location.
11. Click **OK**. The Enter a Label window opens.
12. In the Enter a Label window, type the name of the certificate.
13. Click **OK**. The certificate is added to the key database.

Using the command line

Use the following commands to add a CA certificate using iKeycmd or runmqakm:

- On UNIX, Linux and Windows, issue the following command:

```
runmqckm -cert -add -db filename -pw password -label label -file filename
        -format ascii
```

where:

-db *filename*	is the fully qualified path name of the CMS key database.
-pw *password*	is the password for the CMS key database.
-label *label*	is the label attached to the certificate.
-file *filename*	is the name of the file containing the certificate.
-format *ascii*	is the format of the certificate. The value can be `ascii` for Base64-encoded ASCII or `binary` for Binary DER data. The default is `ascii`.

Exporting a personal certificate from a key repository

Follow this procedure to exporting a personal certificate.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

Perform the following steps on the machine from which you want to export the personal certificate:

1. Start the iKeyman GUI using the **`strmqikm`** command (on Windows UNIX and Linux).
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file from which you want to export the certificate, for example `key.kdb`.
6. Click **Open**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is displayed in the **File Name** field.
8. In the **Key database content** field, select **Personal Certificates** and select the certificate you want to export.
9. Click **Export/Import**. The Export/Import key window opens.
10. Select **Export Key**.
11. Select the **Key file type** of the certificate you want to export, for example **PKCS12**.
12. Type the file name and location to which you want to export the certificate, or click **Browse** to select the name and location.
13. Click **OK**. The Password Prompt window opens. Note that when you export (rather than extract) a certificate, both the public and private parts of the certificate are included. This is why the exported file is protected by a password. When you extract a certificate, only the public part of the certificate is included, so a password is not required.
14. Type a password in the **Password** field, and type it again in the **Confirm Password** field.
15. Click **OK**. The certificate is exported to the file you specified.

Using the command line

Use the following commands to export a personal certificate using iKeycmd:

- On UNIX, Linux and Windows:

```
runmqckm -cert -export -db filename -pw password -label label -type cms
        -target filename -target_pw password -target_type pkcs12
```

where:

`-db` *filename*	is the fully qualified path name of the CMS key database.
`-fips`	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.
`-pw` *password*	is the password for the CMS key database.
`-label` *label*	is the label attached to the certificate.
`-type` *cms*	is the type of the database.
`-target` *filename*	is the fully qualified path name of the destination file.
`-target_pw` *password*	is the password for encrypting the certificate.
`-target_type` *pkcs12*	is the type of the certificate.

Importing a personal certificate into a key repository on UNIX, Linux or Windows systems

Follow this procedure to import a personal certificate

Before importing a personal certificate in PKCS #12 format into the key database file, you must first add the full valid chain of issuing CA certificates to the key database file (see "Adding a CA certificate (or the public part of a self-signed certificate) into a key repository, on UNIX, Linux or Windows systems" on page 690).

PKCS #12 files should be considered temporary and deleted after use.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS-compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

Perform the following steps on the machine to which you want to import the personal certificate:

1. Start the iKeyman GUI using the **strmqikm** command .
2. From the **Key Database File** menu, click **Open**. The Open window displays.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file to which you want to add the certificate, for example `key.kdb`.
6. Click **Open**. The Password Prompt window displays.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file displays in the **File Name** field.
8. In the **Key database content** field, select **Personal Certificates**.
9. If there are certificates in the Personal Certificates view, follow these steps:
   a. Click **Export/Import**. The Export/Import key window is displayed.
   b. Select **Import Key**.
10. If there are no certificates in the Personal Certificates view, click **Import**.
11. Select the **Key file type** of the certificate you want to import, for example PKCS12.
12. Type the certificate file name and location where the certificate is stored, or click **Browse** to select the name and location.
13. Click **OK**. The Password Prompt window displays.
14. In the **Password** field, type the password used when the certificate was exported.
15. Click **OK**. The Change Labels window is displayed. You can change the labels of certificates being imported if, for example, a certificate with the same label already exists in the target key database. Changing certificate labels has no effect on certificate chain validation. To associate the certificate with a particular queue manager or IBM MQ MQI client, IBM MQ uses either the value of the

CERTLABL attribute, if it is set, or the default ibmwebspheremq with the name of the queue manager or IBM MQ MQI client user logon ID appended, all in lowercase. See Digital certificate labels for details.

16. To change a label, select the required label from the **Select a label to change** list. The label is copied into the **Enter a new label** entry field. Replace the label text with that of the new label and click **Apply**.
17. The text in the **Enter a new label** entry field is copied back into the **Select a label to change** field, replacing the originally selected label and so relabelling the corresponding certificate.
18. When you have changed all the labels that needed to be changed, click **OK**. The Change Labels window closes, and the original IBM Key Management window reappears with the **Personal Certificates** and **Signer Certificates** fields updated with the correctly labeled certificates.
19. The certificate is imported to the target key database.

Using the command line

To import a personal certificate using iKeycmd, use the following commands:

- On UNIX, Linux and Windows:

```
runmqckm -cert -import -file filename -pw password -type pkcs12 -target filename
-target_pw password -target_type cms -label label
```

where:

-file *filename*	is the fully qualified file name of the file containing the PKCS #12 certificate.
-pw *password*	is the password for the PKCS #12 certificate.
-type *pkcs12*	is the type of the file.
-target *filename*	is the name of the destination CMS key database.
-target_pw *password*	is the password for the CMS key database.
-target_type *cms*	is the type of the database specified by -target
-label *label*	is the label of the certificate to import from the source key database.
-new_label *label*	is the label that the certificate will be assigned in the target database. If you omit -new_label option, the default is to use the same as the -label option.
-fips	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

iKeycmd does not provide a command to change certificate labels directly. Use the following steps to change a certificate label:

1. Export the certificate to a PKCS #12 file using the **-cert -export** command. Specify the existing certificate label for the -label option.
2. Remove the existing copy of the certificate from the original key database using the **-cert -delete** command.
3. Import the certificate from the PKCS #12 file using the **-cert -import** command. Specify the old label for the -label option and the required new label for the -new_label option. The certificate will be imported back into the key database with the required label.

Importing a personal certificate from a Microsoft.pfx file

Follow this procedure to import from a Microsoft.pfx file.

A .pfx file can contain two certificates relating to the same key. One is a personal or site certificate (containing both a public and private key). The other is a CA (signer) certificate (containing only a public key). These certificates cannot coexist in the same CMS key database file, so only one of them can be imported. Also, the "friendly name" or label is attached to only the signer certificate.

The personal certificate is identified by a system generated Unique User Identifier (UUID). This section shows the import of a personal certificate from a pfx file while labeling it with the friendly name previously assigned to the CA (signer) certificate. The issuing CA (signer) certificates should already be added to the target key database. Note that PKCS#12 files should be considered temporary and deleted after use.

Follow these steps to import a personal certificate from a source pfx key database:

1. Start the iKeyman GUI using the `strmqikm` command (on Linux, UNIX or Windows). The IBM Key Management window is displayed.
2. From the **Key Database File** menu, click **Open**. The Open window is displayed.
3. Select a key database type of **PKCS12**.
4. **You are recommended to take a backup of the pfx database before performing this step.** Select the pfx key database that you want to import. Click **Open**. The Password Prompt window is displayed.
5. Enter the key database password and click **OK**. The IBM Key Management window is displayed. The title bar shows the name of the selected pfx key database file, indicating that the file is open and ready.
6. Select **Signer Certificates** from the list. The "friendly name" of the required certificate is displayed as a label in the Signer Certificates panel.
7. Select the label entry and click **Delete** to remove the signer certificate. The Confirm window is displayed.
8. Click **Yes**. The selected label is no longer displayed in the Signer Certificates panel.
9. Repeat steps 6, 7, and 8 for all the signer certificates.
10. From the **Key Database File** menu, click **Open**. The Open window is displayed.
11. Select the target key CMS database which the pfx file is being imported into. Click **Open**. The Password Prompt window is displayed.
12. Enter the key database password and click **OK**. The IBM Key Management window is displayed. The title bar shows the name of the selected key database file, indicating that the file is open and ready.
13. Select **Personal Certificates** from the list.
14. If there are certificates in the Personal Certificates view, follow these steps:
    a. Click **Export/Import key**. The Export/Import key window is displayed.
    b. Select **Import** from Choose Action Type.
15. If there are no certificates in the Personal Certificates view, click **Import**.
16. Select the PKCS12 file.
17. Enter the name of the pfx file as used in Step 4. Click **OK**. The Password Prompt window is displayed.
18. Specify the same password that you specified when you deleted the signer certificate. Click **OK**.
19. The Change Labels window is displayed (as there should be only a single certificate available for import). The label of the certificate should be a UUID which has a format `xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx`.
20. To change the label select the UUID from the **Select a label to change:** panel. The label will be replicated into the **Enter a new label:** field. Replace the label text with that of the friendly name that

was deleted in Step 7 and click **Apply**. The friendly name must be either the value of the IBM MQ **CERTLABL** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client user logon ID appended, all in lowercase. See Digital certificate labels for details.

21. Click **OK**. The Change Labels window is now removed and the original IBM Key Management window reappears with the Personal Certificates and Signer Certificates panels updated with the correctly labeled personal certificate.
22. The pfx personal certificate is now imported to the (target) database.

It is not possible to change a certificate label using iKeycmd or runmqakm.

Using the command line

To import a personal certificate using iKeycmd, use the following commands:

- On UNIX, Linux and Windows:

```
runmqckm -cert -import -file filename -pw password -type pkcs12 -target filename
-target_pw password -target_type cms -label label -pfx
```

To import a personal certificate using **runmqakm**, use the following command:

```
runmqakm -cert -import -file filename -pw password -type pkcs12 -target filename
-target_pw password -target_type cms -label label -fips -pfx
```

where:

`-file` *filename*	is the fully qualified file name of the file containing the PKCS #12 certificate.
`-pw` *password*	is the password for the PKCS #12 certificate.
`-type` *pkcs12*	is the type of the file.
`-target` *filename*	is the name of the destination CMS key database.
`-target_pw` *password*	is the password for the CMS key database.
`-target_type` *cms*	is the type of the database specified by `-target`
`-label` *label*	is the label of the certificate to import from the source key database.
`-new_label` *label*	is the label that the certificate will be assigned in the target database. If you omit `-new_label` option, the default is to use the same as the `-label` option.
`-fips`	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.
`-pfx`	indicates PFX file format.

iKeycmd does not provide a command to change certificate labels directly. Use the following steps to change a certificate label:

1. Export the certificate to a PKCS #12 file using the **-cert -export** command. Specify the existing certificate label for the `-label` option.
2. Remove the existing copy of the certificate from the original key database using the **-cert -delete** command.
3. Import the certificate from the PKCS #12 file using the **-cert -import** command. Specify the old label for the `-label` option and the required new label for the `-new_label` option. The certificate will be imported back into the key database with the required label.

Importing a personal certificate from a PKCS #7 file

The iKeyman and iKeycmd tools do not support PKCS #7 (`.p7b`) files. Use the runmqckm tool to import certificates from a PKCS #7 file.

Use the following command to add a CA certificate from a PKCS #7 file:

```
runmqckm -cert -add -db filename -pw password -type cms -file filename
-label label
```

`-db` *filename*	is the fully qualified file name of the CMS key database.
`-pw` *password*	is the password for the key database.
`-type` *cms*	is the type of the key database.
`-file` *filename*	is the name of the PKCS #7 file.
`-label` *label*	is the label that the certificate is assigned in the target database. The first certificate takes the label given. All other certificates, if present, are labeled with their subject name.

Use the following command to import a personal certificate from a PKCS #7 file:

```
runmqckm -cert -import -db filename -pw password -type pkcs7 -target filename
-target_pw password -target_type cms -label label -new_label label
```

`-db` *filename*	is the fully qualified file name of the file containing the PKCS #7 certificate.
`-pw` *password*	is the password for the PKCS #7 certificate.
`-type` *pkcs7*	is the type of the file.
`-target` *filename*	is the name of the destination key database.
`-target_pw` *password*	is the password for the destination key database.
`-target_type` *cms*	is the type of the database specified by `-target`
`-label` *label*	is the label of the certificate that is to be imported.
`-new_label` *label*	is the label that the certificate will be assigned in the target database. If you omit the `-new_label` option, the default is to use the same as the `-label` option.

Deleting a certificate from a key repository on UNIX, Linux or Windows systems

Use this procedure to remove personal or CA certificates.

Using iKeyman

If you need to manage SSL certificates in a way that is FIPS compliant, use the runmqakm command. iKeyman does not provide a FIPS-compliant option.

1. Start the iKeyman GUI using the **`strmqikm`** command (on UNIX, Linux and Windows systems).
2. From the **Key Database File** menu, click **Open**. The Open window opens.
3. Click **Key database type** and select **CMS** (Certificate Management System).
4. Click **Browse** to navigate to the directory that contains the key database files.
5. Select the key database file from which you want to delete the certificate, for example `key.kdb`.
6. Click **Open**. The Password Prompt window opens.
7. Type the password you set when you created the key database and click **OK**. The name of your key database file is displayed in the **File Name** field.
8. From the drop down list, select **Personal Certificates** or **Signer Certificates**
9. Select the certificate you want to delete.
10. If you do not already have a copy of the certificate and you want to save it, click **Export/Import** and export it (see "Exporting a personal certificate from a key repository" on page 691).
11. With the certificate selected, click **Delete**. The Confirm window opens.

12. Click **Yes**. The **Personal Certificates** field no longer shows the label of the certificate you deleted.

Using the command line

Use the following commands to delete a certificate using iKeycmd or runmqakm:

- On UNIX, Linux and Windows:

```
runmqckm -cert -delete -db filename -pw password -label label
```

where:

`-db` *filename*	is the fully qualified file name of a CMS key database.
`-pw` *password*	is the password for the CMS key database.
`-label` *label*	is the label attached to the personal certificate.
`-fips`	specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that have been FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

Generating strong passwords for key repository protection

You can generate strong passwords for key repository protection using the **runmqakm** (GSKCapiCmd) command.

You can use the **runmqakm** command with the following parameters to generate a strong password:

```
runmqakm -random -create -length 14 -strong -fips
```

When using the generated password on the **-pw** parameter of subsequent certificate administration commands, always place double quotation marks around the password. On UNIX and Linux systems, you must also use a backslash character to escape the following characters if they appear in the password string:

```
!  \  "  '
```

When entering the password in response to a prompt from **runmqckm**, **runmqakm** or the iKeyman GUI then it is not necessary to quote or escape the password. It is not necessary because the operating system shell does not affect data entry in these cases.

Configuring for cryptographic hardware on UNIX, Linux or Windows systems

You can configure cryptographic hardware for a queue manager or client in a number of ways.

You can configure cryptographic hardware for a queue manager on UNIX, Linux or Windows systems using either of the following methods:

- Use the ALTER QMGR MQSC command with the SSLCRYP parameter, as described in ALTER QMGR.
- Use IBM MQ Explorer to configure the cryptographic hardware on your UNIX, Linux or Windows system. For more information, refer to the online help.

You can configure cryptographic hardware for an IBM MQ client on UNIX, Linux or Windows systems using either of the following methods:

- Set the MQSSLCRYP environment variable. The permitted values for MQSSLCRYP are the same as for the SSLCRYP parameter, as described in ALTER QMGR. If you use the GSK_PCS11 version of the SSLCRYP parameter, the PKCS #11 token label must be specified entirely in lower-case.
- Set the **CryptoHardware** field of the SSL configuration options structure, MQSCO, on an MQCONNX call. For more information, see Overview for MQSCO.

If you have configured cryptographic hardware which uses the PKCS #11 interface using any of these methods, you must store the personal certificate for use on your channels in the key database file for the cryptographic token you have configured. This is described in "Managing certificates on PKCS #11 hardware."

Managing certificates on PKCS #11 hardware:

You can manage digital certificates on cryptographic hardware that supports the PKCS #11 interface.

About this task

You must create a key database to prepare the IBM MQ environment, even if you do not intend to store certificate authority (CA) certificates in it, but will store all your certificates on your cryptographic hardware. A key database is necessary for the queue manager to reference in its SSLKEYR field, or for the client application to reference in the MQSSLKEYR environment variable. This key database is also required if you are creating a certificate request.

Procedure

- To create a key database by using the iKeyman user interface, complete the following steps:
  1. On UNIX and Linux systems, log in as the root user. On Windows systems, log in as Administrator or as a member of the MQM group.
  2. Start the iKeyman user interface by running the **strmqikm** command.
  3. Click **Key Database File** > **Open**.
  4. Click **Key database type** and select **PKCS11Direct**.
  5. In the **File Name** field, type the name of the module for managing your cryptographic hardware; for example, `PKCS11_API.so`.

     If you are using certificates or keys stored on PKCS #11 cryptographic hardware, note that iKeycmd and iKeyman are 64-bit programs. External modules required for PKCS #11 support will be loaded into a 64-bit process, therefore you must have a 64-bit PKCS #11 library installed for the administration of cryptographic hardware. The Windows and Linux x86 32-bit platforms are the only exceptions, as the iKeyman and iKeycmd programs are 32-bit on those platforms.
  6. In the **Location** field, enter the path:
     - On UNIX and Linux systems, this might be `/usr/lib/pksc11`, for example.
     - On Windows systems, you can type the library name; for example, `cryptoki`.

     Click **OK**. The Open Cryptographic Token window opens.
  7. In the **Cryptographic Token Password** field, type the password that you set when you configured the cryptographic hardware.
  8. If your cryptographic hardware has the capacity to hold the signer certificates required to receive or import a personal certificate, clear both secondary key database check boxes and continue from step 12 on page 699. If you require a secondary CMS key database to hold the signer certificates, select either **Open existing secondary key database file** or **Create new secondary key database file**.
  9. In the **File Name** field, type a file name. This field already contains the text `key.kdb`. If your stem name is `key`, leave this field unchanged. If you specified a different stem name, replace `key` with your stem name. You must not change the `.kdb` suffix.
  10. In the **Location** field, type the path, for example:
      - For a queue manager: `/var/mqm/qmgrs/QM1/ssl`
      - For an IBM MQ MQI client: `/var/mqm/ssl`

      Click **OK**. The Password Prompt window opens.
  11. Enter a password.
      - If you selected **Open existing secondary key database file** in step 8, type a password in the **Password** field.
      - If you selected **Create new secondary key database file** in step 8:

   a. Type a password in the **Password** field, and type it again in the **Confirm Password** field.
   b. Select **Stash the password to a file**. Note that if you do not stash the password, attempts to start SSL channels fail because they cannot obtain the password required to access the key database file.
   c. Click **OK**. A window opens, confirming that the password is in file `key.sth` (unless you specified a different stem name).
12. Click **OK**. The Key database content frame displays.

- To create a key database by using the command line, use either of the following commands:
  - On UNIX, Linux, and Windows systems:

    ```
    runmqckm -keydb -create -db filename -pw password -type cms -stash
    ```
  - Using runmqakm:

    ```
    runmqakm -keydb -create -db filename -pw password -type cms
    -stash -fips -strong
    ```

  where:

  -db *filename*
  Specifies the fully qualified file name of a CMS key database, and must have a file extension of `.kdb`.

  -pw *password*
  Specifies the password for the CMS key database.

  -type *cms*
  Specifies the type of database. (For IBM MQ, it must be `cms`.)

  -stash
  Saves the key database password to a file.

  -fips
  Specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that are FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

  -strong
  Checks that the password entered satisfies the minimum requirements for password strength. The minimum requirements for a password are as follows:
  - The password must be a minimum length of 14 characters.
  - The password must contain a minimum of one lowercase character, one uppercase character, and one digit or special character. Special characters include the asterisk (*), the dollar sign ($), the number sign (#), and the percent sign (%). A space is classified as a special character.
  - Each character can occur a maximum of three times in a password.
  - A maximum of two consecutive characters in the password can be identical.
  - All characters are in the standard ASCII printable character set, within the range 0x20 - 0x7E.

Requesting a personal certificate for your PKCS #11 hardware:

Use this procedure for either a queue manager or an IBM MQ MQI client to request a personal certificate for your cryptographic hardware.

Using the iKeyman user interface:
About this task

Note: IBM MQ does not support SHA-3 or SHA-5 algorithms. You can use the digital signature algorithm names SHA384WithRSA and SHA512WithRSA because both algorithms are members of the SHA-2 family.

The digital signature algorithm names SHA3WithRSA and SHA5WithRSA are deprecated because they are an abbreviated form of SHA384WithRSA and SHA512WithRSA respectively.

Procedure

To request a personal certificate from the iKeyman user interface, complete the following steps:
1. Complete the steps to work with your cryptographic hardware. See "Managing certificates on PKCS #11 hardware" on page 698.
2. From the **Create** menu, click **New Certificate Request**. The Create New Key and Certificate Request window opens.
3. In the **Key Label** field, enter the certificate label. The label is either the value of the **`CERTLABL`** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client logon user ID appended, all in lowercase. See Digital certificate labels for details.
4. Enter values for **Common Name** and **Organization**, and select a **Country**. For the remaining optional fields, either accept the default values, or type or select new values. Note that you can supply only one name in the **Organizational Unit** field. For more information about these fields, see "Distinguished Names" on page 384.
5. In the **Enter the name of a file in which to store the certificate request** field, either accept the default `certreq.arm`, or type a new value with a full path.
6. Click **OK**. A confirmation window opens.
7. Click **OK**. The **Personal Certificate Requests** list shows the label of the new personal certificate request you created. The certificate request is stored in the file you chose in step 5.
8. Request the new personal certificate either by sending the file to a certificate authority (CA), or by copying the file into the request form on the website for the CA.

Using the command line:
Procedure

Request a personal certificate by using either the **`runmqckm`** (iKeycmd) or **`runmqakm`** (GSKCapiCmd) command.

- Using **`runmqckm`**:

  ```
  runmqckm -certreq -create -db filename -pw password -label label
          -dn distinguished_name -size key_size
   -file filename -sig_alg algorithm
  ```

  Instead of `-dn` *`distinguished_name`*, you can use `-san_dsname` *`DNS_names`*, `-san_emailaddr` *`email_addresses`*, or `-san_ipaddr` *`IP_addresses`*.
- Using **`runmqakm`**:

  ```
  runmqakm -certreq -create -db filename -pw password -label label
          -dn distinguished_name -size key_size
   -file filename -fips
          -sig_alg algorithm
  ```

where:

-db *filename*
Specifies the fully qualified file name of a CMS key database.

-pw *password*
Specifies the password for the CMS key database.

-label *label*
Specifies the key label attached to the certificate. The label is either the value of the **CERTLABL** attribute, if it is set, or the default ibmwebspheremq with the name of the queue manager or the IBM MQ MQI client logon user ID appended, all in lowercase. See "Digital certificate labels, understanding the requirements" on page 400 for details.

-dn *distinguished_name*
Specifies the X.500 distinguished name enclosed in double quotation marks. At least one attribute is required. You can supply multiple OU and DC attributes.

Note: The **runmqckm** and **runmqakm** tools refer to the postal code attribute as POSTALCODE, not PC. Always specify POSTALCODE in the **-dn** parameter when you use these certificate management commands to request certificates with a postal code.

-size *key_size*
Specifies the key size. If you are using **runmqckm**, the value can be 512 or 1024. If you are using **runmqakm**, the value can be 512, 1024, or 2048.

-file *filename*
Specifies the file name for the certificate request.

-fips
Specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that are FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

-sig_alg
For **runmqckm**, specifies the asymmetric signature algorithm used for the creation of the entry's key pair. The value can be MD2_WITH_RSA, MD2WithRSA, MD5_WITH_RSA, MD5WithRSA, SHA1WithDSA, SHA1WithRSA, SHA256_WITH_RSA, SHA256WithRSA, SHA2WithRSA, SHA384_WITH_RSA, SHA384WithRSA, SHA512_WITH_RSA, SHA512WithRSA, SHA_WITH_DSA, SHA_WITH_RSA, SHAWithDSA, or SHAWithRSA. The default value is SHA1WithRSA

-sig_alg
For **runmqakm**, specifies the hashing algorithm used during the creation of a certificate request. This hashing algorithm is used to create the signature associated with the newly created certificate request. The value can be md5, MD5_WITH_RSA, MD5WithRSA, SHA_WITH_DSA, SHA_WITH_RSA, sha1, SHA1WithDSA, SHA1WithECDSA, SHA1WithRSA, sha224, SHA224_WITH_RSA, SHA224WithDSA, SHA224WithECDSA, SHA224WithRSA, sha256, SHA256_WITH_RSA, SHA256WithDSA, SHA256WithECDSA, SHA256WithRSA, SHA2WithRSA, sha384, SHA384_WITH_RSA, SHA384WithECDSA, SHA384WithRSA, sha512, SHA512_WITH_RSA, SHA512WithECDSA, SHA512WithRSA, SHAWithDSA, SHAWithRSA, EC_ecdsa_with_SHA1, EC_ecdsa_with_SHA224, EC_ecdsa_with_SHA256, EC_ecdsa_with_SHA384, or EC_ecdsa_with_SHA512. The default value is SHA1WithRSA.

-san_dnsname *DNS_names*
Specifies a comma-delimited or space-delimited list of DNS names for the entry being created.

-san_emailaddr *email_addresses*
Specifies a comma-delimited or space-delimited list of email addresses for the entry being created.

-san_ipaddr *IP_addresses*
Specifies a comma-delimited or space-delimited list of IP addresses for the entry being created.

What to do next

Submit a certificate request to a CA. See "Receiving personal certificates into a key repository on UNIX, Linux and Windows systems" on page 687 for further information.

Importing a personal certificate to your PKCS #11 hardware:

Use this procedure for either a queue manager or an IBM MQ MQI client to import a personal certificate to your cryptographic hardware.

Using iKeyman:
Procedure

To request a personal certificate from the iKeyman user interface, complete the following steps:
1. Complete the steps to work with your cryptographic hardware. See "Managing certificates on PKCS #11 hardware" on page 698.
2. Click **Receive**. The Receive Certificate from a File window opens.
3. Select the **Data type** of the new personal certificate; for example, `Base64-encoded ASCII data` for a file with the `.arm` extension.
4. Type the certificate file name and location for the new personal certificate, or click **Browse** to select the name and location.
5. Click **OK**. If you already have a personal certificate in your key database a window opens, asking if you want to set the key you are adding as the default key in the database.
6. Click **Yes** or **No**. The Enter a Label window opens.
7. Enter the certificate label. The label is either the value of the **`CERTLABL`** attribute, if it is set, or the default `ibmwebspheremq` with the name of the queue manager or IBM MQ MQI client logon user ID appended, all in lowercase. See Digital certificate labels for details.
8. Click **OK**. The **Personal Certificates** list shows the label of the new personal certificate you added. This label is formed by adding the cryptographic token label before the label you supplied.

Using the command line:
Procedure

To request a personal certificate from a command line, complete the following steps:
1. Open a command window that is configured for your environment.
2. Enter the appropriate command for your operating system and configuration:
   - On Windows, UNIX and Linux systems, use one of the following commands:

     ```
     runmqckm -cert -receive -file filename -crypto path
     -tokenlabel hardware_token -pw hardware_password
     -format cert_format
     ```

     ```
     runmqakm -cert -receive -file filename -crypto path
     -tokenlabel hardware_token -pw hardware_password
     -format cert_format -fips
     ```

   where:

   `-file` ***`filename`***
   Specifies the fully qualified file name of the file containing the personal certificate.

   `-crypto` ***`path`***
   Specifies the fully qualified path to the PKCS #11 library supplied with the hardware.

   `-tokenlabel` ***`hardware_token`***
   Specifies the label given to the storage part of the cryptographic hardware during installation.

-pw *hardware_password*
Specifies the password for access to the hardware.

-format *cert_format*
Specifies the format of the certificate. The value can be `ascii` for Base64-encoded ASCII or `binary` for binary DER data. The default is ASCII.

-fips
Specifies that the command is run in FIPS mode. When in FIPS mode, the ICC component uses algorithms that are FIPS 140-2 validated. If the ICC component does not initialize in FIPS mode, the **runmqakm** command fails.

Working with TLS on IBM MQ Appliance

IBM MQ Appliance has Transport Layer Security (TLS) support.

The IBM MQ Appliance has distinct commands for managing certificates. For detailed information about certificate management, see the IBM MQ Appliance documentation, TLS certificate management

Working with SSL or TLS on z/OS

z/OS

This information describes how you set up and work with the Secure Sockets Layer (SSL) or Transport Layer Security (TLS) on z/OS.

Each topic includes examples of performing each task using RACF. You can perform similar tasks using the other external security managers.

On z/OS, you must also set the number of server subtasks that each queue manager uses for processing SSL calls, as described in "Setting the SSLTASKS parameter" on page 704.

z/OS SSL support is integral to the operating system, and is known as *System SSL*. System SSL is part of the Cryptographic Services Base element of z/OS. The Cryptographic Services Base members are installed in the *pdsname*. SIEALNKE partitioned data set (PDS). When you install System SSL, ensure that you choose the appropriate options to provide the CipherSpecs that you require.

Additional user ID requirements

z/OS

This information describes the additional requirements your user ID needs to set up and work with the TLS or SSL on z/OS.

Ensure that you have all the appropriate High Impact or Pervasive (HIPER) updates on your system.

Ensure that you have set up the following prerequisites:

- The *ssidCHIN* user ID is defined correctly in RACF, and that the *ssidCHIN* user ID has READ access to the following profiles:
  - IRR.DIGTCERT.LIST
  - IRR.DIGTCERT.LISTRING

  These variables are defined in the RACF FACILITY Class.
- The *ssidCHIN* user ID is the owner of the key ring.
- The personal certificate of the queue manager, if created by the RACDCERT command, is created with a certificate type user ID that is also the same as the *ssidCHIN* user ID.
- The channel initiator is recycled, or the command **REFRESH SECURITY TYPE(SSL)** is issued, to pick up any changes you make to the key ring.

- The IBM MQ Channel Initiator procedure has access to the system SSL runtime library *pdsname*.SIEALNKE through the link list, LPA, or a STEPLIB DD statement. This library must be APF-authorized.
- The user ID under whose authority the channel initiator is running is configured to use UNIX System Services (USS), as described in the z/OS UNIX System Services Planning documentation.

  Users who do not want the channel initiator to invoke UNIX System Services using the guest/default UID and OMVS segment, need only model a new OMVS segment based on the default segment as the channel initiator requires no special permissions, and does not run within UNIX as a superuser.

Setting the SSLTASKS parameter

Use the ALTER QMGR command to set the number of server subtasks for processing SSL calls

To use SSL channels, ensure that there are at least two server subtasks by setting the SSLTASKS parameter, using the ALTER QMGR command. For example:

```
ALTER QMGR SSLTASKS(5)
```

To avoid problems with storage allocation, do not set the SSLTASKS attribute to a value greater than eight in an environment where there is no Certificate Revocation List (CRL) checking.

If CRL checking is used, an SSLTASK is held by the channel concerned for the duration of that check. This could be for a significant elapsed time while the relevant LDAP server is contacted, because each SSLTASK is a z/OS task control block.

You must restart the channel initiator if you change the value of the SSLTASKS attribute.

Setting up a key repository on z/OS

Set up a key repository at both ends of the connection. Associate each key repository with its queue manager.

An SSL or TLS connection requires a *key repository* at each end of the connection. Each queue manager must have access to a key repository. Use the SSLKEYR parameter on the ALTER QMGR command to associate a key repository with a queue manager. See "The SSL or TLS key repository" on page 398 for more information.

On z/OS, digital certificates are stored in a *key ring* that is managed by your External Security Manager (ESM) . These digital certificates have labels, which associate the certificate with a queue manager. SSL and TLS use these certificates for authentication purposes. All the examples that follow use RACF commands. Equivalent commands exist for other ESM programs.

On z/OS, IBM MQ uses either the value of the **`CERTLABL`** attribute, if it is set, or the default `ibmWebSphereMQ` with the name of the queue manager appended. See Digital certificate labels for details.

The key repository name for a queue manager is the name of a key ring in your RACF database. You can specify the key ring name either before or after creating the key ring.

Use the following procedure to create a new key ring for a queue manager:

1. Ensure that you have the appropriate authority to issue the RACDCERT command (see the *SecureWay Security Server RACF Command Language Reference* for more details).
2. Issue the following command:

   ```
   RACDCERT ID( userid1 ) ADDRING( ring-name )
   ```

   where:

   - *userid1* is the user ID of the channel initiator address space, or the user ID that is going to own the key ring (if the key ring is shared).

- *ring-name* is the name you want to give to your key ring. The length of this name can be up to 237 characters. This name is case-sensitive. Specify *ring-name* in uppercase characters to avoid problems.

Making CA certificates available to a queue manager on z/OS:

After you have created your key ring, connect any relevant CA certificates to it.

If you have the CA certificate in a dataset, you must first add the certificate to the RACF® database by using the following command:

```
RACDCERT ID( userid1 ) ADD( input-data-set-name ) WITHLABEL( 'My CA' )
```

Then to connect a CA certificate for `My CA` to your key ring, use the following command:

```
RACDCERT ID(userid1)
CONNECT(CERTAUTH LABEL('My CA') RING(ring-name) USAGE(CERTAUTH))
```

where *userid1* is either the channel initiator user ID or the owner of a shared key ring.

For more information about CA certificates, refer to "Digital certificates" on page 382.

Locating the key repository for a queue manager on z/OS

Use this procedure to obtain the location of your queue manager's key ring.

1. Display your queue manager's attributes, using either of the following MQSC commands:
   ```
   DISPLAY QMGR ALL
   DISPLAY QMGR SSLKEYR
   ```
2. Examine the command output for the location of the key ring.

Specifying the key repository location for a queue manager

To specify the location of your queue manager's key ring, use the ALTER QMGR MQSC command to set your queue manager's key repository attribute.

For example:

```
ALTER QMGR SSLKEYR(CSQ1RING)
```

if the key ring is owned by the channel initiator address space, or:

```
ALTER QMGR SSLKEYR(userid1/CSQ1RING)
```

if it is a shared key ring, where *userid1* is the user ID that owns the key ring.

Giving the channel initiator the correct access rights

The channel initiator (CHINIT) needs access to the key repository and to certain security profiles.

Granting the CHINIT access to read the key repository

If the key repository is owned by the CHINIT user ID, this user ID needs read access to the IRR.DIGTCERT.LISTRING profile in the FACILITY class, and update access otherwise. Grant access by using the PERMIT command with ACCESS(UPDATE) or ACCESS(READ) as appropriate:

```
PERMIT IRR.DIGTCERT.LISTRING CLASS(FACILITY) ID( userid ) ACCESS(UPDATE)
```

where *userid* is the user ID of the channel initiator address space.

Granting the CHINIT read access to the appropriate CSF* profiles

For hardware support provided through the Integrated Cryptographic Service Facility (ICSF) to be used, ensure your CHINIT user ID has read access to the appropriate CSF* profiles in the CSFSERV class by using the following command:

```
PERMIT csf-resource CLASS(CSFSERV) ID( userid ) ACCESS(READ)
```

where *csf-resource* is the name of the CSF* profile and *userid* is the user ID of the channel initiator address space.

Repeat this command for each of the following CSF* profile names:
- CSFPKD
- CSFPKE
- CSFPKI
- CSFDSG
- CSFDSV

If your certificate keys are stored in ICSF and your installation has established access control over keys stored in ICSF, ensure your CHINIT user ID has read access to the profile in the CSFKEYS class by using the following command:

```
PERMIT IRR.DIGTCERT. userid.* CLASS(CSFKEYS) ID( userid ) ACCESS(READ)
```

where *userid* is the user ID of the channel initiator address space.

Using the Integrated Cryptographic Service Facility (ICSF)

The channel initiator can use ICSF to generate a random number when seeding the password protection algorithm to obfuscate passwords flowing over client channels if SSL/TLS is not being used.

For further information, see "Using the Integrated Cryptographic Service Facility (ICSF)" on page 643

When changes to certificates or the key repository become effective on z/OS

Changes become effective when the channel initiator starts or the repository is refreshed.

Specifically, changes to the certificates in the key ring and to the key repository attribute become effective on either of the following occasions:
- When the channel initiator is started or restarted.
- When the REFRESH SECURITY TYPE(SSL) command is issued to refresh the contents of the SSL key repository.

Creating a self-signed personal certificate on z/OS

Use this procedure to create a self-signed personal certificate.

1. Generate a certificate and a public and private key pair using the following command:
   ```
   RACDCERT ID(userid2) GENCERT
   SUBJECTSDN(CN('common-name')
              T('title')
              OU('organizational-unit')
              O('organization')
              L('locality')
              SP('state-or-province')
              C('country'))
   WITHLABEL('label-name')
   ```
2. Connect the certificate to your key ring using the following command:
   ```
   RACDCERT ID(userid1)
   CONNECT(ID(userid2) LABEL('label-name') RING(ring-name) USAGE(PERSONAL))
   ```

where:
- *userid1* is the user ID of the channel initiator address space or owner of the shared key ring.
- *userid2* is the user ID associated with the certificate and must be the user ID of the channel initiator address space.

userid1 and *userid2* can be the same ID.

- *ring-name* is the name you gave the key ring in "Setting up a key repository on z/OS" on page 704.
- *label-name* must be either the value of the IBM MQ **CERTLABL** attribute, if it is set, or the default `ibmWebSphereMQ` with the name of the queue manager appended. See Digital certificate labels for details.

Requesting a personal certificate on z/OS

Apply for a personal certificate using RACF.

To apply for a personal certificate, use RACF as follows:

1. Create a self-signed personal certificate, as in "Creating a self-signed personal certificate on z/OS" on page 706. This certificate provides the request with the attribute values for the Distinguished Name.
2. Create a PKCS #10 Base64-encoded certificate request written to a data set, using the following command:

   ```
   RACDCERT ID(userid2) GENREQ(LABEL(' label_name ')) DSN(' output_data_set_name ')
   ```

   where
   - *userid2* is the user ID associated with the certificate and must be the user ID of the channel initiator address space
   - *label_name* is the label used when creating the self-signed certificate

   See "Digital certificate labels, understanding the requirements" on page 400 for details.
3. Send the data set to a Certificate Authority (CA) to request a new personal certificate.
4. When the signed certificate is returned to you by the Certificate Authority, add the certificate back into the RACF database, using the original label, as described in "Adding personal certificates to a key repository on z/OS" on page 708.

Creating a RACF signed personal certificate

RACF can function as a certificate authority and issue its own CA certificate.

This section uses the term *signer certificate* to denote a CA certificate issued by RACF.

The private key for the signer certificate must be in the RACF database before you carry out the following procedure:

1. Use the following command to generate a personal certificate signed by RACF, using the signer certificate contained in your RACF database:

   ```
   RACDCERT ID(userid2) GENCERT
   SUBJECTSDN(CN('common-name')
             T('title')
             OU('organizational-unit')
             O('organization')
             L('locality')
             SP('state-or-province')
             C('country'))
   WITHLABEL('label-name')
   SIGNWITH(CERTAUTH LABEL('signer-label'))
   ```
2. Connect the certificate to your key ring using the following command:

   ```
   RACDCERT ID(userid1)
   CONNECT(ID(userid2) LABEL('label-name') RING(ring-name) USAGE(PERSONAL))
   ```

where:

- *userid1* is the user ID of the channel initiator address space or owner of the shared key ring.
- *userid2* is the user ID associated with the certificate and must be the user ID of the channel initiator address space.

  userid1 and *userid2* can be the same ID.
- *ring-name* is the name you gave the key ring in "Setting up a key repository on z/OS" on page 704.

- *label-name* must be either the value of the IBM MQ **CERTLABL** attribute, if it is set, or the default `ibmWebSphereMQ` with the name of the queue manager or queue-sharing group appended. See Digital certificate labels for details.
- *signer-label* is the label of your own signer certificate.

Adding personal certificates to a key repository on z/OS

Use this procedure to add or import a personal certificate to a key ring.

After the certificate authority sends you a new personal certificate, add it to the key ring using the following procedure:

1. Add the certificate to the RACF database using the following command:

   ```
   RACDCERT ID( userid2 ) ADD( input-data-set-name ) WITHLABEL(' label-name ')
   ```

2. Connect the certificate to your key ring using the following command:

   ```
   RACDCERT ID( userid1 )
   CONNECT(ID( userid2 ) LABEL(' label-name ') RING( ring-name ) USAGE(PERSONAL))
   ```

where:

- *userid1* is the user ID of the channel initiator address space or owner of the shared key ring.
- *userid2* is the user ID associated with the certificate and must be the user ID of the channel initiator address space.
- *ring-name* is the name you gave the key ring in “Setting up a key repository on z/OS” on page 704.
- *input-data-set-name* is the name of the data set containing the CA signed certificate. The data set must be cataloged and must not be a PDS or a member of a PDS. The record format (RECFM) expected by RACDCERT is VB. RACDCERT dynamically allocates and opens the data set, and reads the certificate from it as binary data.
- *label-name* is the label name that was used when you created the original request. It must be either the value of the IBM MQ **CERTLABL** attribute, if it is set, or the default `ibmWebSphereMQ` with the name of the queue manager or queue-sharing group appended. See Digital certificate labels for details.

Exporting a personal certificate from a key repository on z/OS

Export the certificate using the RACDCERT command.

On the system from which you want to export the certificate, use the following command:

```
RACDCERT ID(userid2) EXPORT(LABEL('label-name'))
DSN(output-data-set-name) FORMAT(CERTB64)
```

where:

- *userid2* is the user ID under which the certificate was added to the key ring.
- *label-name* is the label of the certificate you want to extract.
- *output-data-set-name* is the data set into which the certificate is placed.
- CERTB64 is a DER encoded X.509 certificate that is in Base64 format. You can choose an alternative format, for example:

  CERTDER
  DER encoded X.509 certificate in binary format

  PKCS12B64
  PKCS #12 certificate in Base64 format

  PKCS12DER
  PKCS #12 certificate in binary format

Deleting a personal certificate from a key repository on z/OS

Delete a personal certificate using the RACDCERT command.

Before deleting a personal certificate, you might want to save a copy of it. To copy your personal certificate to a data set before deleting it, follow the procedure in "Exporting a personal certificate from a key repository on z/OS" on page 708. Then use the following command to delete your personal certificate:

```
RACDCERT ID( userid2 ) DELETE(LABEL(' label-name '))
```

where:

- *userid2* is the user ID under which the certificate was added to the key ring.
- *label-name* is the name of the certificate you want to delete.

Renaming a personal certificate in a key repository on z/OS

Rename a certificate using the RACDCERT command.

If you do not want a certificate with a specific label to be found, but do not want to delete it, you can rename it temporarily using the following command:

```
RACDCERT ID( userid2 ) LABEL(' label-name ') NEWLABEL(' new-label-name ')
```

where:

- *userid2* is the user ID under which the certificate was added to the key ring.
- *label-name* is the name of the certificate you want to rename.
- *new-label-name* is the new name of the certificate.

This can be useful when testing SSL client authentication.

Associating a user ID with a digital certificate on z/OS

IBM MQ can use a user ID associated with a RACF certificate as a channel user ID. Associate a user ID with a certificate by installing it under that user ID, or using a Certificate Name Filter.

The method described in this topic is an alternative to the platform-independent method for associating a user ID with a digital certificate, which uses channel authentication records. For more information about channel authentication records, see "Channel authentication records" on page 424.

When an entity at one end of an SSL channel receives a certificate from a remote connection, the entity asks RACF if there is a user ID associated with that certificate. The entity uses that user ID as the channel user ID. If there is no user ID associated with the certificate, the entity uses the user ID under which the channel initiator is running.

Associate a user ID with a certificate in either of the following ways:

- Install that certificate into the RACF database under the user ID with which you want to associate it, as described in "Adding personal certificates to a key repository on z/OS" on page 708.
- Use a Certificate Name Filter (CNF) to map the Distinguished Name of the subject or issuer of the certificate to the user ID, as described in "Setting up a certificate name filter" on page 710.

Setting up a certificate name filter:

Use the RACDCERT command to define a certificate name filter (CNF), which maps a Distinguished Name to a user ID.

Perform the following steps to set up a CNF.

1. Enable CNF functions using the following command. You require update authority on the class DIGTNMAP to do this.
   ```
   SETROPTS CLASSACT(DIGTNMAP) RACLIST(DIGTNMAP)
   ```
2. Define the CNF. For example:
   ```
   RACDCERT ID(USER1) MAP WITHLABEL('filter1') TRUST
   SDNFILTER('O=IBM.C=UK') IDNFILTER('O=ExampleCA.L=Internet')
   ```
   where `USER1` is the user ID to be used when:
   - The DN of the subject has an Organization of `IBM` and a Country of `UK`.
   - The DN of the issuer has an Organization of `ExampleCA` and a Locality of `Internet`.
3. Refresh the CNF mappings:
   ```
   SETROPTS RACLIST(DIGTNMAP) REFRESH
   ```

Note:

1. If the actual certificate is stored in the RACF database, the user ID under which it is installed is used in preference to the user ID associated with any CNF. If the certificate is not stored in the RACF database, the user ID associated with the most specific matching CNF is used. Matches of the subject DN are considered more specific than matches of the issuer DN.
2. Changes to CNFs do not apply until you refresh the CNF mappings.
3. A DN matches the DN filter in a CNF only if the DN filter is identical to the *least significant portion* of the DN. The least significant portion of the DN comprises the attributes that are usually listed at the right-most end of the DN, but which appear at the beginning of the certificate.

   For example, consider the SDNFILTER `'O=IBM.C=UK'`. A subject DN of `'CN=QM1.O=IBM.C=UK'` matches that filter, but a subject DN of `'CN=QM1.O=IBM.L=Hursley.C=UK'` does not match that filter.

   The least significant portion of some certificates can contain fields that do not match the DN filter. Consider excluding these certificates by specifying a DN pattern in the SSLPEER pattern on the DEFINE CHANNEL command.
4. If the most specific matching CNF is defined to RACF as NOTRUST, the entity uses the user ID under which the channel initiator is running.
5. RACF uses the `'.'` character as a separator. IBM MQ uses either a comma or a semicolon.

You can define CNFs to ensure that the entity never sets the channel user ID to the default, which is the user ID under which the channel initiator is running. For each CA certificate in the key ring associated with the entity, define a CNF with an IDNFILTER that exactly matches the subject DN of that CA certificate. This ensures that all certificates that the entity might use match at least one of these CNFs. This is because all such certificates must either be connected to the key ring associated with the entity, or must be issued by a CA for which a certificate is connected to the key ring associated with the entity.

Refer to the *SecureWay Security Server RACF Security Administrator's Guide* for more information about the commands you use to manipulate CNFs.

Defining a sender channel and transmission queue on QMA

Use the **DEFINE CHANNEL** and **DEFINE QLOCAL** commands to set up the required objects.

Procedure

On QMA, issue commands like the following example:

```
DEFINE CHANNEL(TO.QMB) CHLTYPE(SDR) TRPTYPE(TCP) CONNAME(QMB.MACH.COM) XMITQ(QMB)
SSLCIPH(TLS_RSA_WITH_AES_128_CBC_SHA) DESCR('Sender channel using TLS from QMA to QMB')

DEFINE QLOCAL(QMB) USAGE(XMITQ)
```

Results

A sender channel, TO.QMB, and a transmission queue, QMB, are created.

Defining a receiver channel on QMB

Use the **DEFINE CHANNEL** command to set up the required object.

Procedure

On QMB, issue a command like the following example:

```
DEFINE CHANNEL(TO.QMB) CHLTYPE(RCVR) TRPTYPE(TCP) SSLCIPH(TLS_RSA_WITH_AES_128_CBC_SHA)
SSLCAUTH(REQUIRED) DESCR('Receiver channel using TLS to QMB')
```

Results

A receiver channel, TO.QMB, is created.

Starting the sender channel

If necessary, start a listener program and refresh security. Then start the channel using the **START CHANNEL** command.

Procedure

1. Optional: If you have not already done so, start a listener program on QMB. The listener program listens for incoming network requests and starts the receiver channel when it is needed. For information about how to start a listener, see Starting a channel listener.
2. Optional: If any SSL or TLS channels have run previously, issue the command `REFRESH SECURITY TYPE(SSL)`. This ensures that all the changes made to the key repository are available.
3. Start the channel on QMA, using the command `START CHANNEL(TO.QMB)`.

Results

The sender channel is started.

Exchanging self-signed certificates

Exchange the certificates you previously extracted. If you use FTP, use the correct format.

Procedure

Transfer the CA part of the QM1 certificate to the QM2 system and vice versa, for example, by FTP.
If you transfer the certificates using FTP, you must do so in the correct format.
Transfer the following certificate types in *binary* format:

- DER encoded binary X.509
- PKCS #7 (CA certificates)
- PKCS #12 (personal certificates)

Transfer the following certificate types in ASCII format:

- PEM (privacy-enhanced mail)
- Base64 encoded X.509

Defining a sender channel and transmission queue on QM1

Use the **DEFINE CHANNEL** and **DEFINE QLOCAL** commands to set up the required objects.

Procedure

On QM1, issue commands like the following example:

```
DEFINE CHANNEL(QM1.TO.QM2) CHLTYPE(SDR) TRPTYPE(TCP) CONNAME(QM1.MACH.COM) XMITQ(QM2) SSLCIPH(TLS_RSA_WITH_AES_128_CBC_SHA)
```

```
DEFINE QLOCAL(QM2) USAGE(XMITQ)
```

This example uses CipherSpec RC4_MD5. The CipherSpecs at each end of the channel must be the same. Only the SSLCIPH parameter is mandatory if you want your channel to use SSL or TLS. See "CipherSpecs and CipherSuites in IBM MQ" on page 413 for information about the permitted values for the SSLCIPH parameter.

Results

A sender channel, QM1.TO.QM2, and a transmission queue, QM2, are created.

Defining a receiver channel on QM2

Use the **DEFINE CHANNEL** command to set up the required object.

Procedure

On QM2, issue a command like the following example:

```
DEFINE CHANNEL(QM1.TO.QM2) CHLTYPE(RCVR) TRPTYPE(TCP) SSLCIPH(TLS_RSA_WITH_AES_128_CBC_SHA)
SSLCAUTH(REQUIRED) DESCR('Receiver channel using SSL from QM1 to QM2')
```

The channel must have the same name as the sender channel you defined in "Defining a sender channel and transmission queue on QM1," and use the same CipherSpec.

Starting the sender channel

If necessary, start a listener program and refresh security. Then start the channel using the **START CHANNEL** command.

Procedure

1. Optional: If you have not already done so, start a listener program on QM2. The listener program listens for incoming network requests and starts the receiver channel when it is needed. For information about how to start a listener, see Starting a channel listener
2. Optional: If any SSL or TLS channels have run previously, issue the command REFRESH SECURITY TYPE(SSL). This ensures that all the changes made to the key repository are available.
3. On QM1, start the channel, using the command `START CHANNEL(QM1.TO.QM2)`.

Results

The sender channel is started.

Refreshing the SSL or TLS environment

Refresh the SSL or TLS environment on queue manager QMA using the **REFRESH SECURITY** command.

Procedure

On QMA, enter the following command:

```
REFRESH SECURITY TYPE(SSL)
```

This ensures that all the changes made to the key repository are available.

Allowing anonymous connections on a receiver channel

Use the **ALTER CHANNEL** command to make SSL or TLS client authentication optional.

Procedure

On QMB, enter the following command:

```
ALTER CHANNEL(TO.QMB) CHLTYPE(RCVR) SSLCAUTH(OPTIONAL)
```

Starting the sender channel

If necessary, start the channel initiator, start a listener program, and refresh security. Then start the channel using the **START CHANNEL** command.

Procedure

1. Optional: if you have not already done so, start the channel initiator.
2. Optional: If you have not already done so, start a listener program on QM2. The listener program listens for incoming network requests and starts the receiver channel when it is needed. For information about how to start a listener, see Starting a channel listener
3. Optional: If the channel initiator was already running or any SSL or TLS channels have run previously, issue the command REFRESH SECURITY TYPE(SSL). This ensures that all the changes made to the key repository are available.
4. On QM1, start the channel, using the command `START CHANNEL(QM1.TO.QM2)`.

Results

The sender channel is started.

Starting the sender channel on z/OS

If necessary, start the channel initiator, start a listener program, and refresh security. Then start the channel using the **START CHANNEL** command.

Procedure

1. Optional: If you have not already done so, start the channel initiator.
2. Optional: If you have not already done so, start a listener program on QMB. The listener program listens for incoming network requests and starts the receiver channel when it is needed. For information about how to start a listener, see Starting a channel listener.
3. Optional: If the channel initiator was already running or if any SSL or TLS channels have run previously, issue the command `REFRESH SECURITY TYPE(SSL)`. This ensures that all the changes made to the key repository are available.
4. Start the channel on QMA, using the command `START CHANNEL(TO.QMB)`.

Results

The sender channel is started.

Identifying and authenticating users

You can identify and authenticate users by using the MQCSP structure or in several types of user exit program.

Using the MQCSP structure

You specify the MQCSP connection security parameters structure on an MQCONNX call; this structure contains a user ID and password. If necessary, you can alter the MQCSP in a security exit.

Note: The object authority manager (OAM) does not use the password. However the OAM does some limited work with the user ID, that could be considered a trivial form of authentication. These checks stop you adopting another user ID, if you use those parameters in your applications.

Warning: In some cases, the password in an MQCSP structure for a client application will be sent across a network in plain text. To ensure that client application passwords are protected appropriately, see "MQCSP password protection" on page 404.

Implementing identification and authentication in security exits

The primary purpose of a security exit is to enable the MCA at each end of a channel to authenticate its partner. At each end of a message channel, and at the server end of an MQI channel, an MCA typically acts on behalf of the queue manager to which it is connected. At the client end of an MQI channel, an MCA typically acts on behalf of the user of the IBM MQ client application. In this situation, mutual authentication actually takes place between two queue managers, or between a queue manager and the user of an IBM MQ MQI client application.

The supplied security exit (the SSPI channel exit) illustrates how mutual authentication can be implemented by exchanging authentication tokens that are generated, and then checked, by a trusted authentication server such as Kerberos. For more details, see "The SSPI channel exit program" on page 533.

Mutual authentication can also be implemented by using Public Key Infrastructure (PKI) technology. Each security exit generates some random data, signs it using the private key of the queue manager or user it is representing, and sends the signed data to its partner in a security message. The partner security exit performs the authentication by checking the digital signature using the public key of the queue manager or user. Before exchanging digital signatures, the security exits might need to agree the algorithm for generating a message digest, if more than one algorithm is available for use.

When a security exit sends the signed data to its partner, it also needs to send some means of identifying the queue manager or user it is representing. This might be a Distinguished Name, or even a digital certificate. If a digital certificate is sent, the partner security exit can validate the certificate by working through the certificate chain to the root CA certificate. This provides assurance of the ownership of the public key that is used to check the digital signature.

The partner security exit can validate a digital certificate only if it has access to a key repository that contains the remaining certificates in the certificate chain. If a digital certificate for the queue manager or user is not sent, one must be available in the key repository to which the partner security exit has access. The partner security exit cannot check the digital signature unless it can find the signer's public key.

The Secure Sockets Layer (SSL) and Transport Layer Security (TLS) use PKI techniques like the ones just described. For more information about how SSL and TLS perform authentication, see "Secure Sockets Layer (SSL) and Transport Layer Security (TLS) concepts" on page 388.

If a trusted authentication server or PKI support is not available, other techniques can be used. A common technique, which can be implemented in security exits, uses a symmetric key algorithm.

One of the security exits, exit A, generates a random number and sends it in a security message to its partner security exit, exit B. Exit B encrypts the number using its copy of a key which is known only to the two security exits. Exit B sends the encrypted number to exit A in a security message with a second random number that exit B has generated. Exit A verifies that the first random number has been encrypted correctly, encrypts the second random number using its copy of the key, and sends the encrypted number to exit B in a security message. Exit B then verifies that the second random number has been encrypted correctly. During this exchange, if either security exit is not satisfied with the authenticity of other, it can instruct the MCA to close the channel.

An advantage of this technique is that no key or password is sent over the communications connection during the exchange. A disadvantage is that it does not provide a solution to the problem of how to distribute the shared key in a secure way. One solution to this problem is described in "Implementing confidentiality in user exit programs" on page 806. A similar technique is used in SNA for the mutual authentication of two LUs when they bind to form a session. The technique is described in "Session level authentication" on page 493.

All the preceding techniques for mutual authentication can be adapted to provide one-way authentication.

Implementing identification and authentication in message exits

When an application puts a message on a queue, the *UserIdentifier* field in the message descriptor contains a user ID associated with the application. However, there is no data present that can be used to authenticate the user ID. This data can be added by a message exit at the sending end of a channel and checked by a message exit at the receiving end of the channel. The authenticating data can be an encrypted password or a digital signature, for example.

This service might be more effective if it is implemented at the application level. The basic requirement is for the user of the application that receives the message to be able to identify and authenticate the user of the application that sent the message. It is therefore natural to consider implementing this service at the application level. For more information, see "Identity mapping in the API exit and API-crossing exit" on page 720.

Implementing identification and authentication in the API exit and API-crossing exit

At the level of an individual message, identification and authentication is a service that involves two users, the sender and the receiver of the message. The basic requirement is for the user of the application that receives the message to be able to identify and authenticate the user of the application that sent the message. Note that the requirement is for one way, not two way, authentication.

Depending on how it is implemented, the users and their applications might need to interface, or even interact, with the service. In addition, when and how the service is used might depend on where the users and their applications are located, and on the nature of the applications themselves. It is therefore natural to consider implementing the service at the application level rather than at the link level.

If you consider implementing this service at the link level, you might need to resolve issues such as the following:

- On a message channel, how do you apply the service only to those messages that require it?
- How do you enable users and their applications to interface, or interact, with the service, if this is a requirement?

- In a multi-hop situation, where a message is sent over more than one message channel on the way to its destination, where do you invoke the components of the service?

Here are some examples of how the identification and authentication service can be implemented at the application level. The term *API exit* means either an API exit or an API-crossing exit.

- When an application puts a message on a queue, an API exit can acquire an authentication token from a trusted authentication server such as Kerberos. The API exit can add this token to the application data in the message. When the message is retrieved by the receiving application, a second API exit can ask the authentication server to authenticate the sender by checking the token.
- When an application puts a message on a queue, an API exit can append the following items to the application data in the message:
  - The digital certificate of the sender
  - The digital signature of the sender

  If different algorithms for generating a message digest are available for use, the API exit can include the name of the algorithm it has used.

  When the message is retrieved by the receiving application, a second API exit can perform the following checks:
  - The API exit can validate the digital certificate by working through the certificate chain to the root CA certificate. To do this, the API exit must have access to a key repository that contains the remaining certificates in the certificate chain. This check provide assurance that the sender, identified by the Distinguished Name, is the genuine owner of the public key contained in the certificate.
  - The API exit can check the digital signature using the public key contained in the certificate. This check authenticates the sender.

  The Distinguished Name of the sender can be sent instead of the whole digital certificate. In this case, the key repository must contain the sender's certificate so that the second API exit can find the public key of the sender. Another possibility is to send all the certificates in the certificate chain.
- When an application puts a message on a queue, the *UserIdentifier* field in the message descriptor contains a user ID associated with the application. The user ID can be used to identify the sender. To enable authentication, an API exit can append some data, such as an encrypted password, to the application data in the message. When the message is retrieved by the receiving application, a second API exit can authenticate the user ID by using the data that has travelled with the message.

  This technique might be considered sufficient for messages that originate in a controlled and trusted environment, and in circumstances where a trusted authentication server or PKI support is not available.

UNIX Linux V 8.0.0.3

Pluggable Authentication Method (PAM)

PAM is now common across UNIX and Linux platforms, and provides a general mechanism that hides the details of user authentication from services.

Different authentication rules can be used for different services, by configuring the rules, without any change needed to the services themselves.

See "Using the Pluggable Authentication Method (PAM)" on page 732 for further information.

Privileged users

A privileged user is one that has full administrative authorities for IBM MQ.

In addition to the users listed in the following table, members of any group with `+connect` authority for queue managers, and `+crt` authority for queues are indirectly administrators. Similarly, any user that has `+connect` and `+set` authority on the queue manager, and `+put` authority on the command queue is an administrator.

You should not grant these privileges to ordinary users and applications.

Table 78. Privileged users by platform

Platform	Privileged users
Windows systems	• SYSTEM • Members of the mqm group • Members of the Administrators group
UNIX and Linux systems	• Members of the mqm group
IBM i IBM i systems	• The profiles qmqm and qmqmadm • All members of the qmqmadm group • Any user defined with the *ALLOBJ setting
z/OS	The user ID that the channel initiator, queue manager and advanced message security address spaces are running under.

Identifying and authenticating users using the MQCSP structure

You can specify the MQCSP connection security parameters structure on an MQCONNX call.

The MQCSP connection security parameters structure contains a user ID and password, which the authorization service can use to identify and authenticate the user.

The authorization service component supplied with IBM MQ is called the Object Authority Manager (OAM). The OAM authorizes users based on the ID contained in the MQCSP but does not validate the password. It is possible to implement password validation in the authorization service by using chained exits with the OAM, or by replacing the OAM with an alternative authorization service.

You can alter the MQCSP in a security exit.

Warning: In some cases, the password in an MQCSP structure for a client application will be sent across a network in plain text. To ensure that client application passwords are protected appropriately, see "MQCSP password protection" on page 404.

Implementing identification and authentication in security exits

You can use a security exit to implement one-way or mutual authentication.

The primary purpose of a security exit is to enable the MCA at each end of a channel to authenticate its partner. At each end of a message channel, and at the server end of an MQI channel, an MCA typically acts on behalf of the queue manager to which it is connected. At the client end of an MQI channel, an MCA typically acts on behalf of the user of the IBM MQ MQI client application. In this situation, mutual authentication actually takes place between two queue managers, or between a queue manager and the user of an IBM MQ MQI client application.

The supplied security exit (the SSPI channel exit) illustrates how mutual authentication can be implemented by exchanging authentication tokens that are generated, and then checked, by a trusted authentication server such as Kerberos. For more details, see "The SSPI channel exit program" on page 533.

Mutual authentication can also be implemented by using Public Key Infrastructure (PKI) technology. Each security exit generates some random data, signs it using the private key of the queue manager or user it is representing, and sends the signed data to its partner in a security message. The partner security exit performs the authentication by checking the digital signature using the public key of the queue manager or user. Before exchanging digital signatures, the security exits might need to agree the algorithm for generating a message digest, if more than one algorithm is available for use.

When a security exit sends the signed data to its partner, it also needs to send some means of identifying the queue manager or user it is representing. This might be a Distinguished Name, or even a digital certificate. If a digital certificate is sent, the partner security exit can validate the certificate by working through the certificate chain to the root CA certificate. This provides assurance of the ownership of the public key that is used to check the digital signature.

The partner security exit can validate a digital certificate only if it has access to a key repository that contains the remaining certificates in the certificate chain. If a digital certificate for the queue manager or user is not sent, one must be available in the key repository to which the partner security exit has access. The partner security exit cannot check the digital signature unless it can find the signer's public key.

The Secure Sockets Layer (SSL) and Transport Layer Security (TLS) use PKI techniques like the ones just described. For more information about how the Secure Sockets Layer performs authentication, see "Secure Sockets Layer (SSL) and Transport Layer Security (TLS) concepts" on page 388.

If a trusted authentication server or PKI support is not available, other techniques can be used. A common technique, which can be implemented in security exits, uses a symmetric key algorithm.

One of the security exits, exit A, generates a random number and sends it in a security message to its partner security exit, exit B. Exit B encrypts the number using its copy of a key which is known only to the two security exits. Exit B sends the encrypted number to exit A in a security message with a second random number that exit B has generated. Exit A verifies that the first random number has been encrypted correctly, encrypts the second random number using its copy of the key, and sends the encrypted number to exit B in a security message. Exit B then verifies that the second random number has been encrypted correctly. During this exchange, if either security exit is not satisfied with the authenticity of other, it can instruct the MCA to close the channel.

An advantage of this technique is that no key or password is sent over the communications connection during the exchange. A disadvantage is that it does not provide a solution to the problem of how to distribute the shared key in a secure way. One solution to this problem is described in "Implementing confidentiality in user exit programs" on page 806. A similar technique is used in SNA for the mutual authentication of two LUs when they bind to form a session. The technique is described in "Session level authentication" on page 493.

All the preceding techniques for mutual authentication can be adapted to provide one-way authentication.

Identity mapping in message exits

You can use message exits to process information to authenticate a user ID, though it might be better to implement authentication at the application level.

When an application puts a message on a queue, the *UserIdentifier* field in the message descriptor contains a user ID associated with the application. However, there is no data present that can be used to authenticate the user ID. This data can be added by a message exit at the sending end of a channel and checked by a message exit at the receiving end of the channel. The authenticating data can be an encrypted password or a digital signature, for example.

This service might be more effective if it is implemented at the application level. The basic requirement is for the user of the application that receives the message to be able to identify and authenticate the user of the application that sent the message. It is therefore natural to consider implementing this service at the application level. For more information, see "Identity mapping in the API exit and API-crossing exit."

Identity mapping in the API exit and API-crossing exit

An application that receives a message must be able to identify and authenticate the user of the application that sent the message. This service is typically best implemented at the application level. API exits can implement the service in a number of ways.

At the level of an individual message, identification and authentication is a service that involves two users, the sender and the receiver of the message. The basic requirement is for the user of the application that receives the message to be able to identify and authenticate the user of the application that sent the message. Note that the requirement is for one way, not two way, authentication.

Depending on how it is implemented, the users and their applications might need to interface, or even interact, with the service. In addition, when and how the service is used might depend on where the users and their applications are located, and on the nature of the applications themselves. It is therefore natural to consider implementing the service at the application level rather than at the link level.

If you consider implementing this service at the link level, you might need to resolve issues such as the following:

- On a message channel, how do you apply the service only to those messages that require it?
- How do you enable users and their applications to interface, or interact, with the service, if this is a requirement?
- In a multi-hop situation, where a message is sent over more than one message channel on the way to its destination, where do you invoke the components of the service?

Here are some examples of how the identification and authentication service can be implemented at the application level. The term *API exit* means either an API exit or an API-crossing exit.

- When an application puts a message on a queue, an API exit can acquire an authentication token from a trusted authentication server such as Kerberos. The API exit can add this token to the application data in the message. When the message is retrieved by the receiving application, a second API exit can ask the authentication server to authenticate the sender by checking the token.
- When an application puts a message on a queue, an API exit can append the following items to the application data in the message:
  - The digital certificate of the sender
  - The digital signature of the sender

If different algorithms for generating a message digest are available for use, the API exit can include the name of the algorithm it has used.

When the message is retrieved by the receiving application, a second API exit can perform the following checks:

- The API exit can validate the digital certificate by working through the certificate chain to the root CA certificate. To do this, the API exit must have access to a key repository that contains the remaining certificates in the certificate chain. This check provide assurance that the sender, identified by the Distinguished Name, is the genuine owner of the public key contained in the certificate.
- The API exit can check the digital signature using the public key contained in the certificate. This check authenticates the sender.

The Distinguished Name of the sender can be sent instead of the whole digital certificate. In this case, the key repository must contain the sender's certificate so that the second API exit can find the public key of the sender. Another possibility is to send all the certificates in the certificate chain.

- When an application puts a message on a queue, the *UserIdentifier* field in the message descriptor contains a user ID associated with the application. The user ID can be used to identify the sender. To enable authentication, an API exit can append some data, such as an encrypted password, to the application data in the message. When the message is retrieved by the receiving application, a second API exit can authenticate the user ID by using the data that has travelled with the message.

  This technique might be considered sufficient for messages that originate in a controlled and trusted environment, and in circumstances where a trusted authentication server or PKI support is not available.

Working with revoked certificates

Digital certificates can be revoked by Certificate Authorities. You can check the revocation status of certificates using OCSP, or CRLs on LDAP servers, depending on platform.

During the SSL handshake, the communicating partners authenticate each other with digital certificates. Authentication can include a check that the certificate received can still be trusted. Certificate Authorities (CAs) revoke certificates for various reasons, including:

- The owner has moved to a different organization
- The private key is no longer secret

CAs publish revoked personal certificates in a Certificate Revocation List (CRL). CA certificates that have been revoked are published in an Authority Revocation List (ARL).

On the following platforms, IBM MQ SSL support checks for revoked certificates using OCSP (Online Certificate Status Protocol) or using CRLs and ARLs on LDAP (Lightweight Directory Access Protocol) servers. OCSP is the preferred method.

- Linux Linux
- UNIX UNIX
- Windows Windows

IBM MQ classes for Java and IBM MQ classes for JMS cannot use the OCSP information in a client channel definition table file. However, you can configure OCSP as described in Using Online Certificate Protocol.

On the following platforms, and IBM MQ SSL support checks for revoked certificates using CRLs and ARLs on LDAP servers only:

- IBM i IBM i
- z/OS z/OS

For more information about Certificate Authorities, see “Digital certificates” on page 382.

Revoked certificates and OCSP

IBM MQ determines which Online Certificate Status Protocol (OCSP) responder to use, and handles the response received. You might have to take steps to make the OCSP responder accessible.

Note: This information applies only to IBM MQ on Windows, UNIX and Linux systems.

To check the revocation status of a digital certificate using OCSP, IBM MQ can use two methods to determines which OCSP responder to contact:
- By using the AuthorityInfoAccess (AIA) certificate extension in the certificate to be checked.
- By using a URL specified in an authentication information object or specified by a client application.

A URL specified in an authentication information object or by a client application takes priority over a URL in an AIA certificate extension.

If the URL of the OCSP responder lies behind a firewall, reconfigure the firewall so the OCSP responder can be accessed or set up an OCSP proxy server. Specify the name of the proxy server by using the SSLHTTPProxyName variable in the SSL stanza. On client systems, you can also specify the name of the proxy server by using the environment variable MQSSLPROXY. For more details, see the related information.

If you are not concerned whether TLS or SSL certificates are revoked, perhaps because you are running in a test environment, you can set OCSPCheckExtensions to NO in the SSL stanza. If you set this variable, any AIA certificate extension is ignored. This solution is unlikely to be acceptable in a production environment, where you probably do not want to allow access from users presenting revoked certificates.

The call to access the OCSP responder can result in one of the following three outcomes:

Good The certificate is valid.

Revoked
The certificate is revoked.

Unknown
This outcome can arise for one of three reasons:
- IBM MQ cannot access the OCSP responder.
- The OCSP responder has sent a response, but IBM MQ cannot verify the digital signature of the response.
- The OCSP responder has sent a response that indicates that it has no revocation data for the certificate.

If IBM MQ receives an OCSP outcome of `Unknown`, its behavior depends on the setting of the OCSPAuthentication attribute. For queue managers, this attribute is held in the SSL stanza of the `qm.ini` file for UNIX and Linux systems, or the Windows registry. It can be set using the IBM MQ Explorer. For clients, it is held in the SSL stanza of the client configuration file.

If an outcome of `Unknown` is received and OCSPAuthentication is set to REQUIRED (the default value), IBM MQ rejects the connection and issues an error message of type AMQ9716. If queue manager SSL event messages are enabled, an SSL event message of type MQRC_CHANNEL_SSL_ERROR with ReasonQualifier set to MQRQ_SSL_HANDSHAKE_ERROR is generated.

If an outcome of `Unknown` is received and OCSPAuthentication is set to OPTIONAL, IBM MQ allows the SSL channel to start and no warnings or SSL event messages are generated.

If an outcome of `Unknown` is received and OCSPAuthentication is set to WARN, the SSL channel starts but IBM MQ issues a warning message of type AMQ9717 in the error log. If queue manager SSL event messages are enabled, an SSL event message of type

MQRC_CHANNEL_SSL_WARNING with ReasonQualifier set to MQRQ_SSL_UNKNOWN_REVOCATION is generated.

Digital signing of OCSP responses

An OCSP responder can sign its responses in one of three ways. Your responder will inform you which method is used.

- The OCSP response can be digitally signed using the same CA certificate that issued the certificate that you are checking. In this case, you do not need to set up any additional certificate; the steps you have already taken to establish SSL connectivity are sufficient to verify the OCSP response.
- The OCSP response can be digitally signed using another certificate signed by the same certificate authority (CA) that issued the certificate you are checking. The signing certificate is sent together with the OCSP response in this case. The certificate flowed from the OCSP responder must have an Extended Key Usage Extension set to `id-kp-OCSPSigning` so that it can be trusted for this purpose. Because the OCSP response is sent with the certificate which signed it (and that certificate is signed by a CA that is already trusted for SSL connectivity), no additional certificate setup is required.
- The OCSP response can be digitally signed using another certificate that is not directly related to the certificate you are checking. In this case, the OCSP response is signed by a certificate issued by the OCSP responder itself. You must add a copy of the OCSP responder certificate to the key database of the client or queue manager which performs the OCSP checking . When a CA certificate is added, by default it is added as a trusted root, which is the required setting in this context. If this certificate is not added, IBM MQ cannot verify the digital signature on the OCSP response and the OCSP check results in an Unknown outcome, which might cause IBM MQ to close the channel, depending on the value of OCSPAuthentication.

Online Certificate Status Protocol (OCSP) in Java and JMS client applications

Due to a limitation of the Java API, IBM MQ can use Online Certificate Status Protocol (OCSP) certificate revocation checking for SSL and TLS secure sockets only when OCSP is enabled for the entire Java virtual machine (JVM) process. There are two ways to enable OCSP for all secure sockets in the JVM:

- Edit the JRE java.security file to include the OCSP configuration settings that are shown in Table 1 and restart the application.
- Use the java.security.Security.setProperty() API, subject to any Java Security Manager policy in effect.

As a minimum, you must specify one of the ocsp.enable and ocsp.responderURL values.

Property Name	Description
ocsp.enable	This property's value is either `true` or `false`. If `true`, OCSP checking is enabled when doing certificate revocation checking; if `false` or not set, OCSP checking is disabled.
ocsp.responderURL	This property's value is a URL that identifies the location of the OCSP responder. Here is an example; `ocsp.responderURL=http://ocsp.example.net:80`. By default, the location of the OCSP responder is determined implicitly from the certificate that is being validated. The property is used when the Authority Information Access extension (defined in RFC 3280) is absent from the certificate or when it requires overriding.

Property Name	Description
ocsp.responderCertSubjectName	This property's value is the subject name of the OCSP responder's certificate. Here is an example; `ocsp.responderCertSubjectName="CN=OCSP Responder, O=XYZ Corp"`. By default, the certificate of the OCSP responder is that of the issuer of the certificate that is being validated. This property identifies the certificate of the OCSP responder when the default does not apply. Its value is a string distinguished name (defined in RFC 2253) which identifies a certificate in the set of certificates that are supplied during cert path validation. In cases where the subject name alone is not sufficient to uniquely identify the certificate, then both the ocsp.responderCertIssuerName and ocsp.responderCertSerialNumber properties must be used instead. When this property is set, then the properties ocsp.responderCertIssuerName and ocsp.responderCertSerialNumber are ignored.
ocsp.responderCertIssuerName	This property's value is the issuer name of the OCSP responder's certificate. Here is an example; `ocsp.responderCertIssuerName="CN=Enterprise CA, O=XYZ Corp"`. By default, the certificate of the OCSP responder is that of the issuer of the certificate that is being validated. This property identifies the certificate of the OCSP responder when the default does not apply. Its value is a string distinguished name (defined in RFC 2253) which identifies a certificate in the set of certificates that are supplied during cert path validation. When this property is set then the ocsp.responderCertSerialNumber property must also be set. This property is ignored when the ocsp.responderCertSubjectName property is set.
ocsp.responderCertSerialNumber	This property's value is the serial number of the OCSP responder's certificate. Here is an example; `ocsp.responderCertSerialNumber=2A:FF:00`. By default, the certificate of the OCSP responder is that of the issuer of the certificate that is being validated. This property identifies the certificate of the OCSP responder when the default does not apply. This value is a string of hexadecimal digits (colon or space separators might be present) which identifies a certificate in the set of certificates that are supplied during cert path validation. When this property is set then the ocsp.responderCertIssuerName property must also be set. This property is ignored when the ocsp.responderCertSubjectName property is set.

Before you enable OCSP in this way, there are a number of considerations:

- Setting the OCSP configuration affects all secure sockets in the JVM process. In some cases this configuration might have undesirable side-effects when the JVM is shared with other application code that uses SSL or TLS secure sockets. Ensure that the chosen OCSP configuration is suitable for all of the applications that are running in the same JVM.
- Applying maintenance to your JRE might overwrite the java.security file. Take care when you apply Java interim fixes and product maintenance to avoid overwriting the java.security file. It might be necessary to reapply your java.security changes after you apply maintenance. For this reason, you might consider setting the OCSP configuration by using the java.security.Security.setProperty() API instead.

- Enabling OCSP checking has an effect only if revocation checking is also enabled. Revocation checking is enabled by the `PKIXParameters.setRevocationEnabled()` method.
- If you are using the AMS Java Interceptor described in Enabling OCSP checking in native interceptors, take care to avoid using a java.security OCSP configuration that conflicts with the AMS OCSP configuration in the keystore configuration file.

Working with Certificate Revocation Lists and Authority Revocation Lists

IBM MQ support for CRLs and ARLs varies by platform.

CRL and ARL support on each platform is as follows:
- On z/OS, System SSL supports CRLs and ARLs stored in LDAP servers by the Tivoli Public Key Infrastructure product.
- On other platforms, the CRL and ARL support complies with PKIX X.509 V2 CRL profile recommendations.

IBM MQ maintains a cache of CRLs and ARLs that have been accessed in the preceding 12 hours.

When a queue manager or IBM MQ MQI client receives a certificate, it checks the CRL to confirm that the certificate is still valid. IBM MQ first checks in the cache, if there is a cache. If the CRL is not in the cache, IBM MQ interrogates the LDAP CRL server locations in the order they occur in the namelist of authentication information objects specified by the *SSLCRLNamelist* attribute, until IBM MQ finds an available CRL. If the namelist is not specified, or is specified with a blank value, CRLs are not checked.

Setting up LDAP servers

Configure the LDAP Directory Information Tree structure to reflect the hierarchy of Distinguished Names of CAs. Do this using LDAP Data Interchange Format files.

Configure the LDAP Directory Information Tree (DIT) structure to use the hierarchy corresponding to the Distinguished Names of the CAs that issue the certificates and CRLs. You can set up the DIT structure with a file that uses the LDAP Data Interchange Format (LDIF). You can also use LDIF files to update a directory.

LDIF files are ASCII text files that contain the information required to define objects within an LDAP directory. LDIF files contain one or more entries, each of which comprises a Distinguished Name, at least one object class definition and, optionally, multiple attribute definitions.

The `certificateRevocationList;binary` attribute contains a list, in binary form, of revoked user certificates. The `authorityRevocationList;binary` attribute contains a binary list of CA certificates that have been revoked. For use with IBM MQ SSL, the binary data for these attributes must conform to DER (Definite Encoding Rules) format. For more information about LDIF files, refer to the documentation provided with your LDAP server.

Figure 73 on page 726 shows a sample LDIF file that you might create as input to your LDAP server to load the CRLs and ARLs issued by CA1, which is an imaginary Certificate Authority with the Distinguished Name “CN=CA1, OU=Test, O=IBM, C=GB”, set up by the Test organization within IBM.

```
dn: o=IBM, c=GB
o: IBM
objectclass: top
objectclass: organization

dn: ou=Test, o=IBM, c=GB
ou: Test
objectclass: organizationalUnit

dn: cn=CA1, ou=Test, o=IBM, c=GB
cn: CA1
objectclass: cRLDistributionPoint
objectclass: certificateAuthority
authorityRevocationList;binary:: (DER format data)
certificateRevocationList;binary:: (DER format data)
caCertificate;binary:: (DER format data)
```

Figure 73. Sample LDIF file for a Certificate Authority. This might vary from implementation to implementation.

Figure 74 shows the DIT structure that your LDAP server creates when you load the sample LDIF file shown in Figure 73 together with a similar file for CA2, an imaginary Certificate Authority set up by the PKI organization, also within IBM.

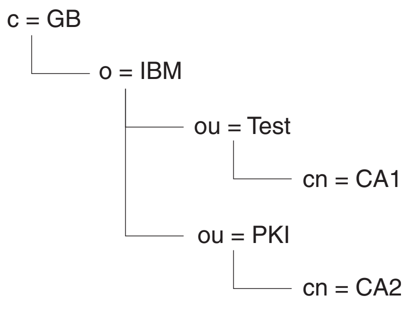

Figure 74. Example of an LDAP Directory Information Tree structure

WebSphere MQ checks both CRLs and ARLs.

Note: Ensure that the access control list for your LDAP server allows authorized users to read, search, and compare the entries that hold the CRLs and ARLs. WebSphere MQ accesses the LDAP server using the LDAPUSER and LDAPPWD properties of the AUTHINFO object.

Configuring and updating LDAP servers:

Use this procedure to configure or update your LDAP server.

1. Obtain the CRLs and ARLs in DER format from your Certification Authority, or Authorities.
2. Using a text editor or the tool provided with your LDAP server, create one or more LDIF files that contain the Distinguished Name of the CA and the required object class definitions. Copy the DER format data into the LDIF file as the values of either the `certificateRevocationList;binary` attribute for CRLs, the `authorityRevocationList;binary` attribute for ARLs , or both.
3. Start your LDAP server.
4. Add the entries from the LDIF file or files you created at step 2.

After you have configured your LDAP CRL server, check that it is set up correctly. First, try using a certificate that is not revoked on the channel, and check that the channel starts correctly. Then use a certificate that is revoked, and check that the channel fails to start.

Obtain updated CRLs from the Certification Authorities frequently. Consider doing this on your LDAP servers every 12 hours.

Accessing CRLs and ARLs with a queue manager

A queue manager is associated with one or more authentication information objects, which hold the address of an LDAP CRL server. IBM i Websphere MQ on IBM i behaves differently from other platforms.

Note that in this section, information about Certificate Revocation Lists (CRLs) also applies to Authority Revocation Lists (ARLs).

You tell the queue manager how to access CRLs by supplying the queue manager with authentication information objects, each of which holds the address of an LDAP CRL server. The authentication information objects are held in a namelist, which is specified in the *SSLCRLNamelist* queue manager attribute.

In the following example, MQSC is used to specify the parameters:

1. Define authentication information objects using the DEFINE AUTHINFO MQSC command, with the AUTHTYPE parameter set to CRLLDAP. IBM i On IBM i, you can also use the CRTMQMAUTI CL command.

   The value CRLLDAP for the AUTHTYPE parameter indicates that CRLs are accessed on LDAP servers. Each authentication information object with type CRLLDAP that you create holds the address of an LDAP server. When you have more than one authentication information object, the LDAP servers to which they point *must* contain identical information. This provides continuity of service if one or more LDAP servers fail.

   z/OS Additionally, on z/OS only, all LDAP servers must be accessed using the same user ID and password. The user ID and password used are those specified in the first AUTHINFO object in the namelist.

   On all platforms, the user ID and password are sent to the LDAP server unencrypted.
2. Using the DEFINE NAMELIST MQSC command, define a namelist for the names of your authentication information objects. z/OS On z/OS, ensure that the NLTYPE namelist attribute is set to AUTHINFO.
3. Using the ALTER QMGR MQSC command, supply the namelist to the queue manager. For example:

   ```
   ALTER QMGR SSLCRLNL(sslcrlnlname)
   ```

   where `sslcrlnlname` is your namelist of authentication information objects.

This command sets a queue manager attribute called *SSLCRLNamelist*. The queue manager's initial value for this attribute is blank.

IBM i On IBM i, you can specify authentication information objects, but the queue manager uses neither authentication information objects nor a namelist of authentication information objects. Only IBM MQ clients that use a client connection table generated by an IBM i queue manager use the authentication information specified for that IBM i queue manager. The *SSLCRLNamelist* queue manager attribute on IBM i determines what authentication information such clients use. See "Accessing CRLs and ARLs on IBM i" for information about telling an IBM i queue manager how to access CRLs.

You can add up to 10 connections to alternative LDAP servers to the namelist, to ensure continuity of service if one or more LDAP servers fail. Note that the LDAP servers *must* contain identical information.

Accessing CRLs and ARLs on IBM i:

Use this procedure to access CRLs or ARLs on IBM i.

Note that in this section, information about Certificate Revocation Lists (CRLs) also applies to Authority Revocation Lists (ARLs).

Follow these steps to set up a CRL location for a specific certificate on IBM i:

1. Access the DCM interface, as described in "Accessing DCM" on page 661.
2. In the **Manage CRL locations** task category in the navigation panel, click **Add CRL location**. The Manage CRL Locations page is displayed in the task frame.
3. In the **CRL Location Name** field, type a CRL location name, for example `LDAP Server #1`
4. In the **LDAP Server** field, type the LDAP server name.
5. In the **Use Secure Sockets Layer (SSL)** field, select **Yes** if you want to connect to the LDAP server using SSL. Otherwise, select **No**.
6. In the **Port Number** field, type a port number for the LDAP server, for example `389`.
7. If your LDAP server does not allow anonymous users to query the directory, type a login distinguished name for the server in the **login distinguished name** field.
8. Click **OK**. DCM informs you that it has created the CRL location.
9. In the navigation panel, click **Select a Certificate Store**. The Select a Certificate Store page is displayed in the task frame.
10. Select the **Other System Certificate Store** check box and click **Continue**. The Certificate Store and Password page is displayed.
11. In the **Certificate store path and filename** field, type the IFS path and file name you set when "Creating a certificate store on IBM i" on page 663.
12. Type a password in the **Certificate Store Password** field. Click **Continue**. The Current Certificate Store page is displayed in the task frame.
13. In the **Manage Certificates** task category in the navigation panel, click **Update CRL location assignment**. The CRL Location Assignment page is displayed in the task frame.
14. Select the radio button for the CA certificate to which you want to assign the CRL location. Click **Update CRL Location Assignment**. The Update CRL Location Assignment page is displayed in the task frame.
15. Select the radio button for the CRL location which you want to assign to the certificate. Click **Update Assignment**. DCM informs you that it has updated the assignment.

Note that DCM allows you to assign a different LDAP server by Certificate Authority.

Accessing CRLs and ARLs using IBM MQ Explorer:

You can use IBM MQ Explorer to tell a queue manager how to access CRLs.

Note that in this section, information about Certificate Revocation Lists (CRLs) also applies to Authority Revocation Lists (ARLs).

Use the following procedure to set up an LDAP connection to a CRL:

1. Ensure that you have started your queue manager.
2. Right-click the **Authentication Information** folder and click **New -> Authentication Information**. In the property sheet that opens:
   a. On the first page **Create Authentication Information**, enter a name for the CRL(LDAP) object.
   b. On the **General** page of **Change Properties**, select the connection type. Optionally you can enter a description.
   c. Select the **CRL(LDAP)** page of **Change Properties**.
   d. Enter the LDAP server name as either the network name or the IP address.
   e. If the server requires login details, provide a user ID and if necessary a password.
   f. Click **OK**.
3. Right-click the **Namelists** folder and click **New -> Namelist**. In the property sheet that opens:
   a. Type a name for the namelist.
   b. Add the name of the CRL(LDAP) object (from step 2a) to the list.
   c. Click **OK**.
4. Right-click the queue manager, select **Properties**, and select the **SSL** page:
   a. Select the **Check certificates received by this queue manager against Certification Revocation Lists** check box.
   b. Type the name of the namelist (from step 3a) in the **CRL Namelist** field.

Accessing CRLs and ARLs with an IBM MQ MQI client

You have three options for specifying the LDAP servers that hold CRLs for checking by an IBM MQ MQI client.

Note that in this section, information about Certificate Revocation Lists (CRLs) also applies to Authority Revocation Lists (ARLs).

The three ways of specifying the LDAP servers are as follows:

- Using a channel definition table
- Using the SSL configuration options structure, MQSCO, on an MQCONNX call
- Using the Active Directory (on Windows systems with Active Directory support)

For more details, refer to the related information.

You can include up to 10 connections to alternative LDAP servers to ensure continuity of service if one or more LDAP servers fail. Note that the LDAP servers *must* contain identical information.

You cannot access LDAP CRLs from an IBM MQ MQI client channel running on Linux (zSeries platform).

Location of an OCSP responder, and of LDAP servers that hold CRLs:

On an IBM MQ MQI client system, you can specify the location of an OCSP responder, and of Lightweight Directory Access Protocol (LDAP) servers that hold certificate revocation lists (CRLs).

You can specify these locations in three ways, listed here in order of decreasing precedence.

IBM i (For IBM i, see Accessing CRLs and ARLs on IBM i.)

When an IBM MQ MQI client application issues an MQCONNX call

You can specify an OCSP responder or an LDAP server holding CRLs on an **MQCONNX** call.

On an **MQCONNX** call, the connect options structure, MQCNO, can reference an SSL configuration options structure, MQSCO. In turn, the MQSCO structure can reference one or more authentication information record structures, MQAIR. Each MQAIR structure contains all the information an IBM MQ MQI client requires to access an OCSP responder or an LDAP server holding CRLs. For example, one of the fields in an MQAIR structure is the URL at which a responder can be contacted. For more information about the MQAIR structure, see MQAIR - Authentication information record.

Using a client channel definition table (ccdt) to access an OCSP responder or LDAP servers

So that an IBM MQ MQI client can access an OCSP responder or LDAP servers that hold CRLs, include the attributes of one or more authentication information objects in a client channel definition table.

On a server queue manager, you can define one or more authentication information objects. The attributes of an authentication object contain all the information that is required to access an OCSP responder (on platforms where OCSP is supported) or an LDAP server that holds CRLs. One of the attributes specifies the OCSP responder URL, another specifies the host address, or IP address of a system on which an LDAP server runs.

An authentication information object with AUTHTYPE(OCSP) does not apply for use on IBM i or z/OS queue managers, but it can be specified on those platforms to be copied to the client channel definition table (CCDT) for client use.

To enable an IBM MQ MQI client to access an OCSP responder or LDAP servers that hold CRLs, the attributes of one or more authentication information objects can be included in a client channel definition table. You can include such attributes in one of the following ways:

On server platforms AIX, HP-UX, Linux, IBM i IBM i, Solaris, and Windows

You can define a namelist that contains the names of one or more authentication information objects. You can then set the queue manager attribute, **SSLCRLNameList**, to the name of this namelist.

If you are using CRLs, more than one LDAP server can be configured to provide higher availability. The intention is that each LDAP server holds the same CRLs. If one LDAP server is unavailable when it is required, an IBM MQ MQI client can attempt to access another.

The attributes of the authentication information objects identified by the namelist are referred to collectively here as the *certificate revocation location*. When you set the queue manager attribute, **SSLCRLNameList**, to the name of the namelist, the certificate revocation location is copied into the client channel definition table associated with the queue manager. If the CCDT can be accessed from a client system as a shared file, or if the CCDT is then copied to a client system, the IBM MQ MQI client on that system can use the certificate revocation location in the CCDT to access an OCSP responder or LDAP servers that hold CRLs.

If the certificate revocation location of the queue manager is changed later, the change is reflected in the CCDT associated with the queue manager. If the queue manager attribute, **SSLCRLNameList**, is set to blank, the certificate revocation location is removed from the CCDT. These changes are not reflected in any copy of the table on a client system.

If you require the certificate revocation location at the client and server ends of an MQI channel to be different, and the server queue manager is the one that is used to create the certificate revocation location, you can do it as follows:

1. On the server queue manager, create the certificate revocation location for use on the client system.
2. Copy the CCDT containing the certificate revocation location to the client system.
3. On the server queue manager, change the certificate revocation location to what is required at the server end of the MQI channel.
4. On the client machine, you can use the **runmqsc** command with the **-n** parameter.

On client platforms AIX, HP-UX, Linux, IBM i IBM i, Solaris, and Windows

You can build a CCDT on the client machine by using the runmqsc command with the **-n** parameter and **DEFINE AUTHINFO** objects in the CCDT file. The order that the objects are defined in is the order in which they are used in the file. Any name that you might use in a **DEFINE AUTHINFO** object is not retained in the file. Only positional numbers are used when you **DISPLAY** the **AUTHINFO** objects in a CCDT file.

Note: If you specify the **-n** parameter, you must not specify any other parameter.

Using Active Directory on Windows

On Windows systems, you can use the **setmqcrl** control command to publish the current CRL information in Active Directory.

Command **setmqcrl** does not publish OCSP information.

For information about this command and its syntax, see setmqcrl.

Accessing CRLs and ARLs with IBM MQ classes for Java and IBM MQ classes for JMS

IBM MQ classes for Java and IBM MQ classes for JMS access CRLs differently from other platforms.

For information about working with CRLs and ARLs with IBM MQ classes for Java, see Using certificate revocation lists

For information about working with CRLs and ARLs with IBM MQ classes for JMS, see SSLCERTSTORES object property

Manipulating authentication information objects

You can manipulate authentication information objects using MQSC or PCF commands, or the Websphere MQ Explorer.

The following MQSC commands act on authentication information objects:
- DEFINE AUTHINFO
- ALTER AUTHINFO
- DELETE AUTHINFO
- DISPLAY AUTHINFO

For a complete description of these commands, see Script (MQSC) Commands.

The following Programmable Command Format (PCF) commands act on authentication information objects:
- Create Authentication Information
- Copy Authentication Information
- Change Authentication Information
- Delete Authentication Information
- Inquire Authentication Information
- Inquire Authentication Information Names

For a complete description of these commands, see Definitions of the Programmable Command Formats.

On platforms where it is available, you can also use the IBM MQ Explorer.

Using the Pluggable Authentication Method (PAM)

UNIX Linux V 8.0.0.3

You can use PAM only on UNIX and Linux platforms. A typical UNIX system has PAM modules that implement the traditional authentication mechanism; however, there might be more. As well as the basic task of validating passwords, PAM modules can also be invoked to carry out additional rules.

Configuration files define which authentication method is to be used for each application . Example applications include the standard terminal login, ftp, and telnet.

The advantage of PAM is that the application does not need to know, or care about, how the user ID is actually being authenticated. As long as the application can provide a correct form of authentication data to PAM, the mechanism behind it is transparent.

The form of authentication data depends upon the system being used. For example, IBM MQ obtains a password through parameters, such as the MQCSP structure used in the MQCONNX API call.

Important: You cannot set the **AUTHENMD** attribute until you install IBM MQ Version 8.0.0, Fix Pack 3, and then restart the queue manager, using a **-e CMDLEVEL=***level* of *802* (on the strmqm command) to set the command level you require.

Configuring your system to use PAM

The service name used by IBM MQ, when invoking PAM, is *ibmmq*.

Note that an IBM MQ installation attempts to maintain a default PAM configuration, that permits connections from operating system users, based on known defaults for the different operating systems.

However, your system administrator must verify that rules defined in the `/etc/pam.conf`, or `/etc/pam.d/ibmmq`, files are still appropriate.

Authorizing access to objects

This section contains information about using the object authority manager and channel exit programs to control access to objects.

On UNIX, Linux, and Windows systems. you control access to objects by using the object authority manager (OAM). This collection of topics contains information about using the command interface to the OAM. It also contains a checklist you can use to determine what tasks to perform to apply security to your system, and considerations for granting users the authority to administer IBM MQ and to work with IBM MQ objects. If the supplied security mechanisms do not meet your needs, you can develop your own channel exit programs.

Controlling access to objects by using the OAM on UNIX, Linux and Windows systems

The object authority manager (OAM) provides a command interface for granting and revoking authority to IBM MQ objects.

You must be suitably authorized to use these commands, as described in “Authority to administer IBM MQ on UNIX, Linux, and Windows systems” on page 777. User IDs that are authorized to administer IBM MQ have *super user* authority to the queue manager, which means that you do not have to grant them further permission to issue any MQI requests or commands.

Giving access to an IBM MQ object on UNIX, Linux, and Windows systems

Use the **setmqaut** control command, the **SET AUTHREC** MQSC command, or the **MQCMD_SET_AUTH_REC** PCF command to give users, and groups of users, access to IBM MQ objects. Note, that on IBM MQ Appliance you can use only the **SET AUTHREC** command.

For a full definition of the **setmqaut** control command and its syntax, see setmqaut.

For a full definition of the **SET AUTHREC** MQSC command and its syntax, see SET AUTHREC.

For a full definition of the **MQCMD_SET_AUTH_REC** PCF command and its syntax, see Set Authority Record.

The queue manager must be running to use this command. When you have changed access for a principal, the changes are reflected immediately by the OAM.

To give users access to an object, you need to specify:

- The name of the queue manager that owns the objects you are working with; if you do not specify the name of a queue manager, the default queue manager is assumed.
- The name and type of the object (to identify the object uniquely). You specify the name as a *profile* ; this is either the explicit name of the object, or a generic name, including wildcard characters. For a detailed description of generic profiles, and the use of wildcard characters within them, see “Using OAM generic profiles on UNIX, Linux, and Windows systems” on page 737.
- One or more principals and group names to which the authority applies.

  If a user ID contains spaces, enclose it in quotation marks when you use this command. On Windows systems, you can qualify a user ID with a domain name. If the actual user ID contains an at sign (@) symbol, replace it with @@ to show that it is part of the user ID, not the delimiter between the user ID and the domain name.

- A list of authorizations. Each item in the list specifies a type of access that is to be granted to that object (or revoked from it). Each authorization in the list is specified as a keyword, prefixed with a plus sign (+) or a minus sign (-). Use a plus sign to add the specified authorization, and a minus sign to remove the authorization. There must be no spaces between the + or - sign and the keyword.

  You can specify any number of authorizations in a single command. For example, the list of authorizations to permit a user or group to put messages on a queue and to browse them, but to revoke access to get messages is:

  ```
  +browse -get +put
  ```

Examples of using the `setmqaut` command

The following examples show how to use the **setmqaut** command to grant and revoke permission to use an object:

```
setmqaut -m saturn.queue.manager -t queue -n RED.LOCAL.QUEUE
        -g groupa +browse -get +put
```

In this example:
- `saturn.queue.manager` is the queue manager name
- `queue` is the object type
- `RED.LOCAL.QUEUE` is the object name
- `groupa` is the identifier of the group with authorizations that are to change
- `+browse -get +put` is the authorization list for the specified queue
  - `+browse` adds authorization to browse messages on the queue (to issue **`MQGET`** with the browse option)
  - `-get` removes authorization to get (**`MQGET`**) messages from the queue
  - `+put` adds authorization to put (**`MQPUT`**) messages on the queue

The following command revokes put authority on the queue MyQueue from principal fvuser and from groups groupa and groupb. On UNIX and Linux systems, this command also revokes put authority for all principals in the same primary group as fvuser.

```
setmqaut -m saturn.queue.manager -t queue -n MyQueue -p fvuser
        -g groupa -g groupb -put
```

Using the `setmqaut` command with a different authorization service

If you are using your own authorization service instead of the OAM, you can specify the name of this service on the **`setmqaut`** command to direct the command to this service. You must specify this parameter if you have multiple installable components running at the same time; if you do not, the update is made to the first installable component for the authorization service. By default, this is the supplied OAM.

Usage notes for SET AUTHREC

The list of authorizations to add and the list of authorizations to remove must not overlap. For example, you cannot add display authority and remove display authority with the same command. This rule applies even if the authorities are expressed using different options. For example, the following command fails because DSP authority overlaps with ALLADM authority:

```
SET AUTHREC PROFILE(*) OBJTYPE(QUEUE) PRINCIPAL(PRINC01) AUTHADD(DSP) AUTHRMV(ALLADM)
```

The exception to this overlap behavior is with the ALL authority. The following command first adds ALL authorities then removes the SETID authority:

```
SET AUTHREC PROFILE(*) OBJTYPE(QUEUE) PRINCIPAL(PRINC01) AUTHADD(ALL) AUTHRMV(SETID)
```

The following command first removes ALL authorities then adds the DSP authority:

```
SET AUTHREC PROFILE(*) OBJTYPE(QUEUE) PRINCIPAL(PRINC01) AUTHADD(DSP) AUTHRMV(ALL)
```

Regardless of the order in which they are provided on the command, the ALL are processed first.

Using OAM generic profiles on UNIX, Linux, and Windows systems

Use OAM generic profiles to set, in a single operation, a user's privileges for many objects; rather than having to issue separate **setmqaut** commands, or **SET AUTHREC** commands, against each individual object when it is created. Note, that on IBM MQ Appliance you can use only the **SET AUTHREC** command.

Using generic profiles in the setmqaut or SET AUTHREC commands, enables you to set a generic authority for all objects that fit that profile.

This collection of topics describes the use of generic profiles in more detail.

Using wildcard characters in OAM profiles

What makes a profile generic is the use of special characters (wildcard characters) in the profile name. For example, the question mark (?) wildcard character matches any single character in a name. So, if you specify `ABC.?EF`, the authorization you give to that profile applies to any objects with the names `ABC.DEF`, `ABC.CEF`, `ABC.BEF`, and so on.

The wildcard characters available are:

? Use the question mark (?) instead of any single character. For example, `AB.?D` applies to the objects `AB.CD`, `AB.ED`, and `AB.FD`.

* Use the asterisk (*) as:

- A *qualifier* in a profile name to match any one qualifier in an object name. A qualifier is the part of an object name delimited by a period. For example, in `ABC.DEF.GHI`, the qualifiers are `ABC`, `DEF`, and `GHI`.

  For example, `ABC.*.JKL` applies to the objects `ABC.DEF.JKL`, and `ABC.GHI.JKL`. (Note that it does **not** apply to `ABC.JKL` ; * used in this context always indicates one qualifier.)
- A character within a qualifier in a profile name to match zero or more characters within the qualifier in an object name.

  For example, `ABC.DE*.JKL` applies to the objects `ABC.DE.JKL`, `ABC.DEF.JKL`, and `ABC.DEGH.JKL`.

** Use the double asterisk (**) **once** in a profile name as:

- The entire profile name to match all object names. For example if you use `-t prcs` to identify processes, then use ** as the profile name, you change the authorizations for all processes.
- As either the beginning, middle, or ending qualifier in a profile name to match zero or more qualifiers in an object name. For example, `**.ABC` identifies all objects with the final qualifier ABC.

Note: When using wildcard characters on UNIX and Linux systems, you **must** enclose the profile name in single quotation marks.

Profile priorities

An important point to understand when using generic profiles is the priority that profiles are given when deciding what authorities to apply to an object being created. For example, suppose that you have issued the commands:

```
setmqaut -n AB.* -t q +put -p fred
setmqaut -n AB.C* -t q +get -p fred
```

The first gives put authority to all queues for the principal fred with names that match the profile AB.*; the second gives get authority to the same types of queue that match the profile AB.C*.

Suppose that you now create a queue called AB.CD. According to the rules for wildcard matching, either setmqaut could apply to that queue. So, does it have put or get authority?

To find the answer, you apply the rule that, whenever multiple profiles can apply to an object, **only the most specific applies**. The way that you apply this rule is by comparing the profile names from left to right. Wherever they differ, a non-generic character is more specific then a generic character. So, in this example, the queue AB.CD has **get** authority (AB.C* is more specific than AB.*).

When you are comparing generic characters, the order of *specificity* is:
1. ?
2. *
3. **

Dumping profile settings

For a full definition of the **dmpmqaut** control command and its syntax, see dmpmqaut.

For a full definition of the **DISPLAY AUTHREC** MQSC command and its syntax, see DISPLAY AUTHREC.

For a full definition of the **MQCMD_INQUIRE_AUTH_RECS** PCF command and its syntax, see Inquire Authority Records.

The following examples show the use of the **dmpmqaut** control command to dump authority records for generic profiles:
1. This example dumps all authority records with a profile that matches queue a.b.c for principal user1.
   ```
   dmpmqaut -m qm1 -n a.b.c -t q -p user1
   ```
   The resulting dump looks something like this:
   ```
   profile:     a.b.*
   object type: queue
   entity:      user1
   type:        principal
   authority:   get, browse, put, inq
   ```
   Note: Although UNIX and Linux users can use the `-p` option for the **dmpmqaut** command, they must use `-g groupname` instead when defining authorizations.
2. This example dumps all authority records with a profile that matches queue a.b.c.
   ```
   dmpmqaut -m qmgr1 -n a.b.c -t q
   ```
   The resulting dump looks something like this:
   ```
   profile:     a.b.c
   object type: queue
   entity:      Administrator
   type:        principal
   authority:   all
   - - - - - - - - - - - - - - - - -
   profile:     a.b.*
   object type: queue
   entity:      user1
   type:        principal
   authority:   get, browse, put, inq
   - - - - - - - - - - - - - - - - -
   profile:     a.**
   object type: queue
   entity:      group1
   type:        group
   authority:   get
   ```
3. This example dumps all authority records for profile a.b.*, of type queue.

```
dmpmqaut -m qmgr1 -n a.b.* -t q
```

The resulting dump looks something like this:

```
profile:     a.b.*
object type: queue
entity:      user1
type:        principal
authority:   get, browse, put, inq
```

4. This example dumps all authority records for queue manager qmX.

```
dmpmqaut -m qmX
```

The resulting dump looks something like this:

```
profile:     q1
object type: queue
entity:      Administrator
type:        principal
authority:   all
- - - - - - - - - - - - - - - - - -
profile:     q*
object type: queue
entity:      user1
type:        principal
authority:   get, browse
- - - - - - - - - - - - - - - - - -
profile:     name.*
object type: namelist
entity:      user2
type:        principal
authority:   get
- - - - - - - - - - - - - - - - - -
profile:     pr1
object type: process
entity:      group1
type:        group
authority:   get
```

5. This example dumps all profile names and object types for queue manager qmX.

```
dmpmqaut -m qmX -l
```

The resulting dump looks something like this:

```
profile: q1, type: queue
profile: q*, type: queue
profile: name.*, type: namelist
profile: pr1, type: process
```

Note: For IBM MQ for Windows only, all principals displayed include domain information, for example:

```
profile:     a.b.*
object type: queue
entity:      user1@domain1
type:        principal
authority:   get, browse, put, inq
```

Using wildcard characters in OAM profiles

Use wildcard characters in an object authority manager (OAM) profile name to make that profile applicable to more than one object.

What makes a profile generic is the use of special characters (wildcard characters) in the profile name. For example, the question mark (?) wildcard character matches any single character in a name. So, if you specify `ABC.?EF`, the authorization you give to that profile applies to any objects with the names `ABC.DEF`, `ABC.CEF`, `ABC.BEF`, and so on.

The wildcard characters available are:

?
: Use the question mark (?) instead of any single character. For example, `AB.?D` applies to the objects `AB.CD`, `AB.ED`, and `AB.FD`.

*
: Use the asterisk (*) as:
- A *qualifier* in a profile name to match any one qualifier in an object name. A qualifier is the part of an object name delimited by a period. For example, in `ABC.DEF.GHI`, the qualifiers are `ABC`, `DEF`, and `GHI`.

  For example, `ABC.*.JKL` applies to the objects `ABC.DEF.JKL`, and `ABC.GHI.JKL`. (Note that it does **not** apply to `ABC.JKL` ; * used in this context always indicates one qualifier.)
- A character within a qualifier in a profile name to match zero or more characters within the qualifier in an object name.

  For example, `ABC.DE*.JKL` applies to the objects `ABC.DE.JKL`, `ABC.DEF.JKL`, and `ABC.DEGH.JKL`.

**
: Use the double asterisk (**) **once** in a profile name as:
- The entire profile name to match all object names. For example if you use `-t prcs` to identify processes, then use ** as the profile name, you change the authorizations for all processes.
- As either the beginning, middle, or ending qualifier in a profile name to match zero or more qualifiers in an object name. For example, `**.ABC` identifies all objects with the final qualifier ABC.

Note: When using wildcard characters on UNIX and Linux systems, you **must** enclose the profile name in single quotation marks.

Profile priorities

More than one generic profile can apply to a single object. Where this is the case, the most specific rule applies.

An important point to understand when using generic profiles is the priority that profiles are given when deciding what authorities to apply to an object being created. For example, suppose that you have issued the commands:

```
setmqaut -n AB.* -t q +put -p fred
setmqaut -n AB.C* -t q +get -p fred
```

The first gives put authority to all queues for the principal fred with names that match the profile AB.*; the second gives get authority to the same types of queue that match the profile AB.C*.

Suppose that you now create a queue called AB.CD. According to the rules for wildcard matching, either setmqaut could apply to that queue. So, does it have put or get authority?

To find the answer, you apply the rule that, whenever multiple profiles can apply to an object, **only the most specific applies**. The way that you apply this rule is by comparing the profile names from left to right. Wherever they differ, a non-generic character is more specific then a generic character. So, in this example, the queue AB.CD has **get** authority (AB.C* is more specific than AB.*).

When you are comparing generic characters, the order of *specificity* is:

1. ?
2. *
3. **

See SET AUTHREC for the equivalent information when using this MQSC command.

Dumping profile settings

Use the **dmpmqaut** control command, the **DISPLAY AUTHREC** MQSC command, or the **MQCMD_INQUIRE_AUTH_RECS** PCF command to dump the current authorizations associated with a specified profile. Note, that on IBM MQ Appliance you can use only the **DISPLAY AUTHREC** command.

For a full definition of the **dmpmqaut** control command and its syntax, see dmpmqaut.

For a full definition of the **DISPLAY AUTHREC** MQSC command and its syntax, see DISPLAY AUTHREC.

For a full definition of the **MQCMD_INQUIRE_AUTH_RECS** PCF command and its syntax, see Inquire Authority Records.

The following examples show the use of the **dmpmqaut** control command to dump authority records for generic profiles:

1. This example dumps all authority records with a profile that matches queue a.b.c for principal user1.

   ```
   dmpmqaut -m qm1 -n a.b.c -t q -p user1
   ```

   The resulting dump looks something like this example:

   ```
   profile:     a.b.*
   object type: queue
   entity:      user1
   type:        principal
   authority:   get, browse, put, inq
   ```

   Note: UNIX and Linux users cannot use the `-p` option; they must use `-g groupname` instead.
2. This example dumps all authority records with a profile that matches queue a.b.c.

   ```
   dmpmqaut -m qmgr1 -n a.b.c -t q
   ```

   The resulting dump looks something like this example:

   ```
   profile:     a.b.c
   object type: queue
   entity:      Administrator
   type:        principal
   authority:   all
   - - - - - - - - - - - - - - - - -
   profile:     a.b.*
   object type: queue
   entity:      user1
   type:        principal
   authority:   get, browse, put, inq
   - - - - - - - - - - - - - - - - -
   profile:     a.**
   object type: queue
   entity:      group1
   type:        group
   authority:   get
   ```
3. This example dumps all authority records for profile a.b.*, of type queue.

   ```
   dmpmqaut -m qmgr1 -n a.b.* -t q
   ```

   The resulting dump looks something like this example:

```
profile:     a.b.*
object type: queue
entity:      user1
type:        principal
authority:   get, browse, put, inq
```

4. This example dumps all authority records for queue manager qmX.

   ```
   dmpmqaut -m qmX
   ```

   The resulting dump looks something like this example:

   ```
   profile:     q1
   object type: queue
   entity:      Administrator
   type:        principal
   authority:   all
   - - - - - - - - - - - - - - - - -
   profile:     q*
   object type: queue
   entity:      user1
   type:        principal
   authority:   get, browse
   - - - - - - - - - - - - - - - - -
   profile:     name.*
   object type: namelist
   entity:      user2
   type:        principal
   authority:   get
   - - - - - - - - - - - - - - - - -
   profile:     pr1
   object type: process
   entity:      group1
   type:        group
   authority:   get
   ```

5. This example dumps all profile names and object types for queue manager qmX.

   ```
   dmpmqaut -m qmX -l
   ```

   The resulting dump looks something like this example:

   ```
   profile: q1, type: queue
   profile: q*, type: queue
   profile: name.*, type: namelist
   profile: pr1, type: process
   ```

Note: For IBM MQ for Windows only, all principals displayed include domain information, for example:

```
profile:     a.b.*
object type: queue
entity:      user1@domain1
type:        principal
authority:   get, browse, put, inq
```

Displaying access settings

Use the **dspmqaut** control command, the **DISPLAY AUTHREC** MQSC command, or the **MQCMD_INQUIRE_ENTITY_AUTH** PCF command to view the authorizations that a specific principal or group has for a particular object. Note, that on IBM MQ Appliance you can use only the **DISPLAY AUTHREC** command.

The queue manager must be running to use this command. When you change access for a principal, the changes are reflected immediately by the OAM. Authorization can be displayed for only one group or principal at a time.

For a full definition of the **dmpmqaut** control command and its syntax, see dmpmqaut.

For a full definition of the **DISPLAY AUTHREC** MQSC command and its syntax, see DISPLAY AUTHREC.

For a full definition of the **MQCMD_INQUIRE_AUTH_RECS** PCF command and its syntax, see Inquire Authority Records.

The following example shows the use of the **dspmqaut** control command to display the authorizations that the group `GpAdmin` has to a process definition named `Annuities` that is on queue manager `QueueMan1`.

```
dspmqaut -m QueueMan1 -t process -n Annuities -g GpAdmin
```

Changing and revoking access to an IBM MQ object

To change the level of access that a user or group has to an object, use the **setmqaut** control command, the **DELETE AUTHREC** MQSC command, or the **MQCMD_DELETE_AUTH_REC** PCF command. Note, that on IBM MQ Appliance you can use only the **DELETE AUTHREC** command.

The process of removing the user from a group is described in:
- “Creating and managing groups on Windows” on page 512
- “Creating and managing groups on HP-UX” on page 514
- “Creating and managing groups on AIX” on page 515
- “Creating and managing groups on Solaris” on page 517
- “Creating and managing groups on Linux” on page 517

.

The user ID that creates an IBM MQ object is granted full control authorities to that object. If you remove this user ID from the local mqm group (or the Administrators group on Windows systems) these authorities are not revoked. Use the **setmqaut** control command or the **MQCMD_DELETE_AUTH_REC** PCF command to revoke access to an object for the user ID that created it, after removing it from the mqm or Administrators group.

For a full definition of the setmqaut control command and its syntax, see setmqaut.

For a full definition of the **DELETE AUTHREC** MQSC command and its syntax, see DELETE AUTHREC.

For a full definition of the **MQCMD_DELETE_AUTH_REC** PCF command and its syntax, see Delete Authority Record.

On Windows, from IBM MQ Version 8.0, you can delete the OAM entries corresponding to a particular Windows user account at any time using the **-u** *SID* parameter of **setmqaut**.

Prior to IBM MQ Version 8.0, you had to delete the OAM entries corresponding to a particular Windows user account before deleting the user profile. It was impossible to remove the OAM entries after removing the user account.

Preventing security access checks on Windows, UNIX and Linux systems

To turn off all security checking you can disable the OAM. This might be suitable for a test environment. Having disabled or removed the OAM, you cannot add an OAM to an existing queue manager.

If you decide that you do not want to perform security checks (for example, in a test environment), you can disable the OAM in one of two ways:

- Before you create a queue manager, set the operating system environment variable MQSNOAUT (if you do this, you cannot add an OAM later):

  See Environment variables for information about the implications of setting the MQSNOAUT variable, and how you set MQSNOAUT on Windows and UNIX platforms.
- Edit the queue manager configuration file to remove the service. (If you do this, you cannot add an OAM later.)

If you use setmqaut, or dspmqaut while the OAM is disabled, note the following points:

- The OAM does not validate the specified principal, or group, meaning that the command can accept invalid values.
- The OAM does not perform security checks and indicates that all principals and groups are authorized to perform all applicable object operations.

When an OAM is removed, it cannot be put back on an existing queue manager. This is because the OAM needs to be in place at object creation time. To use the IBM MQ OAM again after it has been removed, the queue manager needs to be rebuilt.

Installable services

Granting required access to resources

Use this topic to determine what tasks to perform to apply security to your IBM MQ system.

About this task

During this task, you decide what actions are necessary to apply the appropriate level of security to the elements of your IBM MQ installation. Each individual task you are referred to gives step-by-step instructions for all platforms.

Procedure

1. Do you need to limit access to your queue manager to certain users?
   a. No: Take no further action.
   b. Yes: Go to the next question.
2. Do these users need partial administrative access on a subset of queue manager resources?
   a. No: Go to the next question.
   b. Yes: See “Granting partial administrative access on a subset of queue manager resources” on page 745.
3. Do these users need full administrative access on a subset of queue manager resources?
   a. No: Go to the next question.
   b. Yes: See “Granting full administrative access on a subset of queue manager resources” on page 753.
4. Do these users need read only access to all queue manager resources?
   a. No: Go to the next question.

   b. Yes: See “Granting read-only access to all resources on a queue manager” on page 757.
5. Do these users need full administrative access on all queue manager resources?
   a. No: Go to the next question.
   b. Yes: See “Granting full administrative access to all resources on a queue manager” on page 759.
6. Do you need user applications to connect to your queue manager?
   a. No: Disable connectivity, as described in “Removing connectivity to the queue manager” on page 760
   b. Yes: See “Allowing user applications to connect to your queue manager” on page 760.

Granting partial administrative access on a subset of queue manager resources

You need to give certain users partial administrative access to some, but not all, queue manager resources. Use this table to determine the actions you need to take.

Table 79. Granting partial administrative access to a subset of queue manager resources

The users need to administer objects of this type	Perform this action
Queues	Grant partial administrative access to the required queues, as described in “Granting limited administrative access to some queues” on page 746
Topics	Grant partial administrative access to the required topics, as described in “Granting limited administrative access to some topics” on page 747
Channels	Grant partial administrative access to the required channels, as described in “Granting limited administrative access to some channels” on page 748
The queue manager	Grant partial administrative access to the queue manager, as described in “Granting limited administrative access to a queue manager” on page 749
Processes	Grant partial administrative access to the required processes, as described in “Granting limited administrative access to some processes” on page 750
Namelists	Grant partial administrative access to the required namelists, as described in “Granting limited administrative access to some namelists” on page 751
Services	Grant partial administrative access to the required services, as described in “Granting limited administrative access to some services” on page 752

Granting limited administrative access to some queues

Grant partial administrative access to some queues on a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to some queues for some actions, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:

  ```
  setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName ReqdAction
  ```

- IBM i For IBM i, issue the following command:

  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
  ```

- z/OS For z/OS, issue the following commands: z/OS

  ```
  RDEFINE MQADMIN QMgrName.QUEUE. ObjectProfile UACC(NONE)
  PERMIT QMgrName.QUEUE. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  These commands grant access to the specified queue. To determine which MQSC commands the user can perform on the queue, issue the following commands for each MQSC command:

  ```
  RDEFINE MQCMDS QMgrName. ReqdAction. QType UACC(NONE)
  PERMIT QMgrName. ReqdAction. QType CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
  ```

  To permit the user to use the DISPLAY QUEUE command, issue the following commands:

  ```
  RDEFINE MQCMDS QMgrName.DISPLAY. QType UACC(NONE)
  PERMIT QMgrName.DISPLAY. QType CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

  ReqdAction
  The action you are allowing the group to take:
  - On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +dlt, +dsp. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.
  - IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMDLT, *ADMDSP. The authorization *ALLADM is equivalent to all these individual authorizations.
  - z/OS On z/OS, one of the values ALTER, CLEAR, DELETE, or MOVE.

  Note: Granting +crt for queues indirectly makes the user or group an administrator. Do not use +crt authority to grant limited administrative access to some queues.

QType

For the DISPLAY command, one of the values QUEUE, QLOCAL, QALIAS, QMODEL, QREMOTE, or QCLUSTER.

For other values of *ReqdAction*, one of the values QLOCAL, QALIAS, QMODEL, or QREMOTE.

Granting limited administrative access to some topics

Grant partial administrative access to some topics on a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to some topics for some actions, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:

  ```
  setmqaut -m QMgrName -n ObjectProfile -t topic -g GroupName ReqdAction
  ```

- IBM i For IBM i, issue the following command:

  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*TOPIC) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
  ```

- z/OS For z/OS, issue the following commands: z/OS

  ```
  RDEFINE MQADMIN QMgrName.TOPIC. ObjectProfile UACC(NONE)
  PERMIT QMgrName.TOPIC. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  These commands grant access to the specified topic. To determine which MQSC commands the user can perform on the topic, issue the following commands for each MQSC command:

  ```
  RDEFINE MQCMDS QMgrName. ReqdAction.TOPIC UACC(NONE)
  PERMIT QMgrName. ReqdAction.TOPIC CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
  ```

  To permit the user to use the DISPLAY TOPIC command, issue the following commands:

  ```
  RDEFINE MQCMDS QMgrName.DISPLAY.TOPIC UACC(NONE)
  PERMIT QMgrName.DISPLAY.TOPIC CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
  ```

  The variable names have the following meanings:

  QMgrName

  The name of the queue manager. z/OS On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile

  The name of the object or generic profile for which to change authorizations.

  GroupName

  The name of the group to be granted access.

  ReqdAction

  The action you are allowing the group to take:

  – On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +crt, +dlt, +dsp. +ctrl. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.

- IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMCRT, *ADMDLT, *ADMDSP, *CTRL. The authorization *ALLADM is equivalent to all these individual authorizations.
- z/OS On z/OS, one of the values ALTER, CLEAR, DEFINE, DELETE, or MOVE.

Granting limited administrative access to some channels

Grant partial administrative access to some channels on a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to some channels for some actions, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:

```
setmqaut -m QMgrName -n ObjectProfile -t channel -g GroupName ReqdAction
```

- IBM i For IBM i, issue the following command:

```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*CHL) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
```

- z/OS For z/OS, issue the following commands: z/OS

```
RDEFINE MQADMIN QMgrName.CHANNEL. ObjectProfile UACC(NONE)
PERMIT QMgrName.CHANNEL. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
```

  These commands grant access to the specified channel. To determine which MQSC commands the user can perform on the channel, issue the following commands for each MQSC command:

```
RDEFINE MQCMDS QMgrName. ReqdAction.CHANNEL UACC(NONE)
PERMIT QMgrName. ReqdAction.CHANNEL CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
```

  To permit the user to use the DISPLAY CHANNEL command, issue the following commands:

```
RDEFINE MQCMDS QMgrName.DISPLAY.CHANNEL UACC(NONE)
PERMIT QMgrName.DISPLAY.CHANNEL CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

  ReqdAction
  The action you are allowing the group to take:

  - On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +crt, +dlt, +dsp. +ctrl, +ctrlx. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.

- – IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMCRT, *ADMDLT, *ADMDSP, *CTRL, *CTRLx. The authorization *ALLADM is equivalent to all these individual authorizations.
- – z/OS On z/OS, one of the values ALTER, CLEAR, DEFINE, DELETE, or MOVE.

Granting limited administrative access to a queue manager

Grant partial administrative access to a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to perform some actions on the queue manager, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t qmgr -g GroupName ReqdAction
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*MQM) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
  ```

Results

To determine which MQSC commands the user can perform on the queue manager, issue the following commands for each MQSC command:

```
RDEFINE MQCMDS QMgrName. ReqdAction.QMGR UACC(NONE)
PERMIT QMgrName. ReqdAction.QMGR CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
```

To permit the user to use the DISPLAY QMGR command, issue the following commands:

```
RDEFINE MQCMDS QMgrName.DISPLAY.QMGR UACC(NONE)
PERMIT QMgrName.DISPLAY.QMGR CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

ReqdAction
The action you are allowing the group to take:

- On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +crt, +dlt, +dsp. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.

  Although +set is an MQI authorization and not normally considered administrative, granting +set on the queue manager can indirectly lead to full administrative authority. Do not grant +set to ordinary users and applications.

- IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMCRT, *ADMDLT, *ADMDSP. The authorization *ALLADM is equivalent to all these individual authorizations.

Granting limited administrative access to some processes

Grant partial administrative access to some processes on a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to some processes for some actions, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t process -g GroupName ReqdAction
  ```
- IBM i For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*PRC) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
  ```
- z/OS For z/OS, issue the following commands: z/OS
  ```
  RDEFINE MQADMIN QMgrName.PROCESS. ObjectProfile UACC(NONE)
  PERMIT QMgrName.PROCESS. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  These commands grant access to the specified channel. To determine which MQSC commands the user can perform on the channel, issue the following commands for each MQSC command:
  ```
  RDEFINE MQCMDS QMgrName. ReqdAction.PROCESS UACC(NONE)
  PERMIT QMgrName. ReqdAction.PROCESS CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
  ```

  To permit the user to use the DISPLAY PROCESS command, issue the following commands:
  ```
  RDEFINE MQCMDS QMgrName.DISPLAY.PROCESS UACC(NONE)
  PERMIT QMgrName.DISPLAY.PROCESS CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. z/OS On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

  ReqdAction
  The action you are allowing the group to take:
  - On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +crt, +dlt, +dsp. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.
  - IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMCRT, *ADMDLT, *ADMDSP. The authorization *ALLADM is equivalent to all these individual authorizations.

  - z/OS On z/OS, one of the values ALTER, CLEAR, DEFINE, DELETE, or MOVE.

Granting limited administrative access to some namelists

Grant partial administrative access to some namelists on a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to some namelists for some actions, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:

```
setmqaut -m QMgrName -n ObjectProfile -t namelist -g GroupName ReqdAction
```

- IBM i For IBM i, issue the following command:

```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*NMLIST) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
```

- z/OS For z/OS, issue the following commands: z/OS

```
RDEFINE MQADMIN QMgrName.NAMELIST. ObjectProfile UACC(NONE)
PERMIT QMgrName.NAMELIST. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
```

  z/OS These commands grant access to the specified namelist. To determine which MQSC commands the user can perform on the namelist, issue the following commands for each MQSC command: z/OS

```
RDEFINE MQCMDS QMgrName. ReqdAction.NAMELIST UACC(NONE)
PERMIT QMgrName. ReqdAction.NAMELIST CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
```

  z/OS To permit the user to use the DISPLAY NAMELIST command, issue the following commands: z/OS

```
RDEFINE MQCMDS QMgrName.DISPLAY.NAMELIST UACC(NONE)
PERMIT QMgrName.DISPLAY.NAMELIST CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. z/OS On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

  ReqdAction
  The action you are allowing the group to take:
  - On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +crt, +dlt, +ctrl, +ctrlx, +dsp. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.

- IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMCRT, *ADMDLT, *ADMDSP, *CTRL, *CTRLX. The authorization *ALLADM is equivalent to all these individual authorizations.
- z/OS On z/OS, one of the values ALTER, CLEAR, DEFINE, DELETE, or MOVE.

Granting limited administrative access to some services

Grant partial administrative access to some services on a queue manager, to each group of users with a business need for it.

About this task

To grant limited administrative access to some services for some actions, use the appropriate commands for your operating system.

Note: Service objects do not exist on z/OS.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:

```
setmqaut -m QMgrName -n ObjectProfile -t service -g GroupName ReqdAction
```

- For IBM i, issue the following command:

```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*SVC) USER(GroupName) AUT(ReqdAction) MQMNAME(' QMgrName ')
```

Results

These commands grant access to the specified service. To determine which MQSC commands the user can perform on the service, issue the following commands for each MQSC command:

```
RDEFINE MQCMDS QMgrName. ReqdAction.SERVICE UACC(NONE)
PERMIT QMgrName. ReqdAction.SERVICE CLASS(MQCMDS) ID(GroupName) ACCESS(ALTER)
```

To permit the user to use the DISPLAY SERVICE command, issue the following commands:

```
RDEFINE MQCMDS QMgrName.DISPLAY.SERVICE UACC(NONE)
PERMIT QMgrName.DISPLAY.SERVICE CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

ReqdAction
The action you are allowing the group to take:

- On UNIX, Linux and Windows systems, any combination of the following authorizations: +chg, +clr, +crt, +dlt, +ctrl, +ctrlx, +dsp. The authorization +alladm is equivalent to +chg +clr +dlt +dsp.

- IBM i On IBM i, any combination of the following authorizations: *ADMCHG, *ADMCLR, *ADMCRT, *ADMDLT, *ADMDSP, *CTRL, *CTRLX. The authorization *ALLADM is equivalent to all these individual authorizations.

Granting full administrative access on a subset of queue manager resources

You need to give certain users full administrative access to some, but not all, queue manager resources. Use these tables to determine the actions you need to take.

Table 80. Granting full administrative access to a subset of queue manager resources

The users need to administer objects of this type	Perform this action
Queues	Grant full administrative access to the required queues, as described in “Granting full administrative access to some queues”
Topics	Grant full administrative access to the required topics, as described in “Granting full administrative access to some topics” on page 754
Channels	Grant full administrative access to the required channels, as described in “Granting full administrative access to some channels” on page 754
The queue manager	Grant full administrative access to the queue manager, as described in “Granting full administrative access to a queue manager” on page 755
Processes	Grant full administrative access to the required processes, as described in “Granting full administrative access to some processes” on page 756
Namelists	Grant full administrative access to the required namelists, as described in “Granting full administrative access to some namelists” on page 756
Services	Grant full administrative access to the required services, as described in “Granting full administrative access to some services” on page 757

Granting full administrative access to some queues

Grant full administrative access to some queues on a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to some queues, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
```
setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +alladm
```
- For IBM i, issue the following command:
```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*ALLADM) MQMNAME(' QMgrName ')
```
- For z/OS, issue the following commands:

```
RDEFINE MQADMIN QMgrName.QUEUE. ObjectProfile UACC(NONE)
PERMIT QMgrName.QUEUE. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

Granting full administrative access to some topics

Grant full administrative access to some topics on a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to some topics for some actions, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t topic -g GroupName +alladm
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*TOPIC) USER(GroupName) AUT(ALLADM) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQADMIN QMgrName.TOPIC. ObjectProfile UACC(NONE)
  PERMIT QMgrName.TOPIC. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting full administrative access to some channels

Grant full administrative access to some channels on a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to some channels, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t channel -g GroupName +alladm
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*CHL) USER(GroupName) AUT(ALLADM) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQADMIN QMgrName.CHANNEL. ObjectProfile UACC(NONE)
  PERMIT QMgrName.CHANNEL. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting full administrative access to a queue manager

Grant full administrative access to a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to the queue manager, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -t qmgr -g GroupName +alladm
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*MQM) USER(GroupName) AUT(*ALLADM) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQADMIN QMgrName.QMGR UACC(NONE)
  PERMIT QMgrName.QMGR CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting full administrative access to some processes

Grant full administrative access to some processes on a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to some processes, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t process -g GroupName +alladm
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*PRC) USER(GroupName) AUT(*ALLADM) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQADMIN QMgrName.CHANNEL. ObjectProfile UACC(NONE)
  PERMIT QMgrName.PROCESS. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting full administrative access to some namelists

Grant full administrative access to some namelists on a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to some namelists, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t namelist -g GroupName +alladm
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*NMLIST) USER(GroupName) AUT(*ALLADM) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQADMIN QMgrName.NAMELIST. ObjectProfile UACC(NONE)
  PERMIT QMgrName.NAMELIST. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
  ```

The variable names have the following meanings:

QMgrName
The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

Granting full administrative access to some services

Grant full administrative access to some services on a queue manager, to each group of users with a business need for it.

About this task

To grant full administrative access to some services, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
```
setmqaut -m QMgrName -n ObjectProfile -t service -g GroupName +alladm
```
- For IBM i, issue the following command:
```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*SVC) USER(GroupName) AUT(*ALLADM) MQMNAME(' QMgrName ')
```
- For z/OS, issue the following commands:
```
RDEFINE MQADMIN QMgrName.SERVICE. ObjectProfile UACC(NONE)
PERMIT QMgrName.SERVICE. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

Granting read-only access to all resources on a queue manager

Grant read-only access to all the resources on a queue manager, to each user or group of users with a business need for it.

About this task

Use the Add Role Based Authorities wizard or the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- Using the wizard:
  1. In the IBM MQ Explorer Navigator pane, right-click the queue manager and click **Object Authorities** > **Add Role Based Authorities** The Add Role Based Authorities wizard opens.
- For UNIX and Windows systems, issue the following commands:

```
setmqaut -m QMgrName -n ** -t queue -g GroupName +browse +dsp
setmqaut -m QMgrName -n SYSTEM.ADMIN.COMMAND.QUEUE -t queue -g GroupName +dsp +inq +put
setmqaut -m QMgrName -n SYSTEM.MQEXPLORER.REPLY.MODEL -t queue -g GroupName +dsp +inq +get
setmqaut -m QMgrName -n ** -t topic -g GroupName +dsp
setmqaut -m QMgrName -n ** -t channel -g GroupName +dsp +inq
setmqaut -m QMgrName -n ** -t clntconn -g GroupName +dsp
setmqaut -m QMgrName -n ** -t authinfo -g GroupName +dsp
setmqaut -m QMgrName -n ** -t listener -g GroupName +dsp
setmqaut -m QMgrName -n ** -t namelist -g GroupName +dsp
setmqaut -m QMgrName -n ** -t process -g GroupName +dsp
setmqaut -m QMgrName -n ** -t service -g GroupName +dsp
setmqaut -m QMgrName -t qmgr -g GroupName +dsp +inq +connect
```

  The specific authorities to SYSTEM.ADMIN.COMMAND.QUEUE and SYSTEM.MQEXPLORER.REPLY.MODEL are necessary only if you want to use the MQ Explorer.
- For IBM i, issue the following commands:

```
GRTMQMAUT OBJ(*ALL) OBJTYPE(*Q) USER('GroupName') AUT(*ADMDSP *BROWSE) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*TOPIC) USER('GroupName') AUT(*ADMDSP) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*CHL) USER('GroupName') AUT(*ADMDSP *INQ) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*CLTCN) USER('GroupName') AUT(*ADMDSP) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*AUTHINFO) USER('GroupName') AUT(*ADMDSP) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*LSR) USER('GroupName') AUT(*ADMDSP)MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*NMLIST) USER('GroupName') AUT(*ADMDSP) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*PRC) USER('GroupName') AUT(*ADMDSP) MQMNAME('QMgrName')
GRTMQMAUT OBJ(*ALL) OBJTYPE(*SVC) USER('GroupName') AUT(*ADMDSP) MQMNAME('QMgrName')
GRTMQMAUT OBJ('object-name') OBJTYPE(*MQM) USER('GroupName') AUT(*ADMDSP *CONNECT *INQ) MQMNAME('QMgrName')
```

- For z/OS, issue the following commands:

```
RDEFINE MQQUEUE QMgrName.** UACC(NONE)
PERMIT QMgrName.** CLASS(MQQUEUE) ID(GroupName) ACCESS(READ)
RDEFINE MQTOPIC QMgrName.** UACC(NONE)
PERMIT QMgrName.** CLASS(MQTOPIC) ID(GroupName) ACCESS(READ)
RDEFINE MQPROC QMgrName.** UACC(NONE)
PERMIT QMgrName.** CLASS(MQPROC) ID(GroupName) ACCESS(READ)
RDEFINE MQNLIST QMgrName.** UACC(NONE)
PERMIT QMgrName.** CLASS(MQNLIST) ID(GroupName) ACCESS(READ)
RDEFINE MQCONN QMgrName.BATCH UACC(NONE)
PERMIT QMgrName.BATCH CLASS(MQCONN) ID(GroupName) ACCESS(READ)
RDEFINE MQCONN QMgrName.CICS UACC(NONE)
PERMIT QMgrName.CICS CLASS(MQCONN) ID(GroupName) ACCESS(READ)
RDEFINE MQCONN QMgrName.IMS UACC(NONE)
PERMIT QMgrName.IMS CLASS(MQCONN) ID(GroupName) ACCESS(READ)
RDEFINE MQCONN QMgrName.CHIN UACC(NONE)
PERMIT QMgrName.CHIN CLASS(MQCONN) ID(GroupName) ACCESS(READ)
```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  GroupName
  The name of the group to be granted access.

Granting full administrative access to all resources on a queue manager

Grant full administrative access to all the resources on a queue manager, to each user or group of users with a business need for it.

About this task

Use the Add Role Based Authorities wizard or the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- Using the wizard:
  1. In the IBM MQ Explorer Navigator pane, right-click the queue manager and click **Object Authorities** > **Add Role Based Authorities** The Add Role Based Authorities wizard opens.
- For UNIX and Linux systems, issue the following commands:

```
setmqaut -m QMgrName -n '**' -t queue -g GroupName +alladm +browse
setmqaut -m QMgrName -n @class -t queue -g GroupName +crt
setmqaut -m QMgrName -n SYSTEM.ADMIN.COMMAND.QUEUE -t queue -g GroupName +dsp +inq +put
setmqaut -m QMgrName -n SYSTEM.MQEXPLORER.REPLY.QUEUE -t queue -g GroupName +dsp +inq +get
setmqaut -m QMgrName -n '**' -t topic -g GroupName +alladm
setmqaut -m QMgrName -n @class -t topic -g GroupName +crt
setmqaut -m QMgrName -n '**' -t channel -g GroupName +alladm
setmqaut -m QMgrName -n @class -t channel -g GroupName +crt
setmqaut -m QMgrName -n '**' -t clntconn -g GroupName +alladm
setmqaut -m QMgrName -n @class -t clntconn -g GroupName +crt
setmqaut -m QMgrName -n '**' -t authinfo -g GroupName +alladm
setmqaut -m QMgrName -n @class -t authinfo -g GroupName +crt
setmqaut -m QMgrName -n '**' -t listener -g GroupName +alladm
setmqaut -m QMgrName -n @class -t listener -g GroupName +crt
setmqaut -m QMgrName -n '**' -t namelist -g GroupName +alladm
setmqaut -m QMgrName -n @class -t namelist -g GroupName +crt
setmqaut -m QMgrName -n '**' -t process -g GroupName +alladm
setmqaut -m QMgrName -n @class -t process -g GroupName +crt
setmqaut -m QMgrName -n '**' -t service -g GroupName +alladm
setmqaut -m QMgrName -n @class -t service -g GroupName +crt
setmqaut -m QMgrName -t qmgr -g GroupName +alladm +conn
```

- For Windows systems, issue the same commands as for UNIX and Linux systems, but using the profile name @CLASS instead of @class.
- For IBM i, issue the following command:

```
GRTMQMAUT OBJ(*ALL) OBJTYPE(*ALL) USER(' GroupName ') AUT(*ALLADM) MQMNAME(' QMgrName ')
```

- For z/OS, issue the following commands:

```
RDEFINE MQADMIN QMgrName.*.** UACC(NONE)
PERMIT QMgrName.*.** CLASS(MQADMIN) ID(GroupName) ACCESS(ALTER)
```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  GroupName
  The name of the group to be granted access.

Removing connectivity to the queue manager

If you do not want user applications to connect to your queue manager, remove their authority to connect to it.

About this task

Revoke the authority of all users to connect to the queue manager by using the appropriate command for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the DELETE AUTHREC command.

Note: On IBM MQ Appliance you can use only the **DELETE AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -t qmgr -g GroupName -connect
  ```
- For IBM i, issue the following command:
  ```
  RVKMQMAUT OBJ (' QMgrName ') OBJTYPE(*MQM) USER(*ALL) AUT(*CONNECT)
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQCONN QMgrName.BATCH UACC(NONE)
  RDEFINE MQCONN QMgrName.CHIN UACC(NONE)
  RDEFINE MQCONN QMgrName.CICS UACC(NONE)
  RDEFINE MQCONN QMgrName.IMS UACC(NONE)
  ```
  Do not issue any PERMIT commands. The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  GroupName
  The name of the group to be denied access.

Allowing user applications to connect to your queue manager

You want to allow user application to connect to your queue manager. Use the tables in this topic to determine what actions to take.

First, determine whether client applications will connect to your queue manager.

If none of the applications that will connect to your queue manager are client applications, disable remote access as described in “Disabling remote access to the queue manager” on page 768.

If one or more of the applications that will connect to your queue manager are client applications, secure remote connectivity as described in “Securing remote connectivity to the queue manager” on page 761.

In both cases, set up connection security as described in “Setting up connection security” on page 768

If you want to control access to resources for each user connecting to the queue manager, see the following table. If the statement in the first column is true, take the action listed in the second column.

Statement	Take this action
You have applications that make use of queues	See "Controlling user access to queues" on page 769
You have applications that make use of topics	See "Controlling user access to topics" on page 773.
You have applications that inquire on the queue manager object	See "Granting authority to inquire on a queue manager" on page 775.
You have applications that use process objects	See "Granting authority to access processes" on page 776
You have applications that make use of namelists	See "Granting authority to access namelists" on page 776

Securing remote connectivity to the queue manager

You can secure remote connectivity to the queue manager using SSL or TLS, a security exit, channel authentication records, or a combination of these methods.

About this task

You connect a client to the queue manager by using a client-connection channel on the client workstation and a server-connection channel on the server. Secure such connections in one of the following ways.

Procedure

1. Using SSL or TLS with channel authentication records:
   a. Prevent any Distinguished Name (DN) from opening a channel, by using an SSLPEERMAP channel authentication record to map all DNs to USERSRC(NOACCESS).
   b. Allow specific DNs or sets of DNs to open a channel by using an SSLPEERMAP channel authentication record to map them to USERSRC(CHANNEL).
2. Using SSL or TLS with a security exit:
   a. Set MCAUSER on the server-connection channel to a user identifier with no privileges.
   b. Write a security exit to assign an MCAUSER value depending on the value of SSL DN it receives in the SSLPeerNamePtr and SSLPeerNameLength fields passed to the exit in the MQCD structure.
3. Using SSL or TLS with fixed channel definition values:
   a. Set SSLPEER on the server-connection channel to a specific value or narrow range of values.
   b. Set MCAUSER on the server-connection channel to the user ID the channel should run with.
4. Using channel authentication records on channels that do not use SSL or TLS:
   a. Prevent any IP address from opening channels, by using an address-mapping channel authentication record with ADDRESS(*) and USERSRC(NOACCESS).
   b. Allow specific IP addresses to open channels, by using address-mapping channel authentication records for those addresses with USERSRC(CHANNEL).
5. Using a security exit:
   a. Write a security exit to authorize connections based on any property you choose, for example, the originating IP address.
6. It is also possible to use channel authentication records with a security exit, or to use all three methods, if your particular circumstances require it.

Blocking specific IP addresses:

You can prevent a specific channel accepting an inbound connection from an IP address, or prevent the whole queue manager from allowing access from an IP address, by using a channel authentication record.

Before you begin

Enable channel authentication records by running the following command:

```
ALTER QMGR CHLAUTH(ENABLED)
```

About this task

To disallow specific channels from accepting an inbound connection and ensure that connections are only accepted when using the correct channel name, one type of rule can be used to block IP addresses. To disallow an IP address access to the whole queue manager, you would normally use a firewall to permanently block it. However, another type of rule can be used to allow you to block a few addresses temporarily, for example while you are waiting for the firewall to be updated.

Procedure

To block IP addresses from using a specific channel, set a channel authentication record by using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**.

```
SET CHLAUTH(generic-channel-name) TYPE(ADDRESSMAP) ADDRESS(generic-ip-address)
USERSRC(NOACCESS)
```

There are three parts to the command:

SET CHLAUTH (*generic-channel-name*)
: You use this part of the command to control whether you want to block a connection for the entire queue manager, single channel or range of channels. What you put in here determines which areas are covered.

  For example:

  - `SET CHLAUTH('*')` - blocks every channel on a queue manager, that is, the entire queue manager
  - SET CHLAUTH('SYSTEM.*') - blocks every channel that begins with SYSTEM.
  - SET CHLAUTH('SYSTEM.DEF.SVRCONN') - blocks the channel SYSTEM.DEF.SVRCONN

Type of CHLAUTH rule
: Use this part of the command to specify the type of command and determines whether you want to supply a single address or list of addresses.

  For example:

  - `TYPE(ADDRESSMAP)` - Use ADDRESSMAP if you want to supply a single address or wild card address. For example, `ADDRESS('192.168.*')` blocks any connections coming from an IP address starting in `192.168`.

    For more information about filtering IP addresses with patterns, see Generic IP addresses.
  - `TYPE(BLOCKADDR)` - Use BLOCKADDR if you want to supply a list of address to block.

Additional parameters
: These parameters are dependent upon the type of rule you used in the second part of the command:

  - For `TYPE(ADDRESSMAP)` you use ADDRESS
  - For `TYPE(BLOCKADDR)` you use ADDRLIST

Related information:
SET CHLAUTH

Temporarily blocking specific IP addresses if the queue manager is not running:

You might want to block particular IP addresses, or ranges of addresses, when the queue manager is not running and you cannot therefore issue MQSC commands. You can temporarily block IP addresses on an exceptional basis by modifying the `blockaddr.ini` file.

About this task

The `blockaddr.ini` file contains a copy of the BLOCKADDR definitions that are used by the queue manager. This file is read by the listener if the listener is started before the queue manager. In these circumstances, the listener uses any values that you have manually added to the `blockaddr.ini` file.

However, be aware that when the queue manager is started, it writes the set of BLOCKADDR definitions to the `blockaddr.ini` file, over-writing any manual editing you might have done. Similarly, every time you add or delete a BLOCKADDR definition by using the **SET CHLAUTH** command, the `blockaddr.ini` file is updated. You can therefore make permanent changes to the BLOCKADDR definitions only by using the **SET CHLAUTH** command when the queue manager is running.

Procedure
1. Open the `blockaddr.ini` file in a text editor. The file is located in the data directory of the queue manager.
2. Add IP addresses as simple keyword-value pairs, where the keyword is `Addr`. For information about filtering IP addresses with patterns, see Generic IP addresses. For example:
   ```
   Addr = 192.0.2.0
   Addr = 192.0.*
   Addr = 192.0.2.1-8
   ```

Related tasks:
"Blocking specific IP addresses" on page 762
You can prevent a specific channel accepting an inbound connection from an IP address, or prevent the whole queue manager from allowing access from an IP address, by using a channel authentication record.

Related information:
SET CHLAUTH

Blocking specific user IDs:

You can prevent specific users from using a channel by specifying user IDs that, if asserted, cause the channel to end. Do this by setting a channel authentication record.

Before you begin

Ensure that channel authentication records are enabled as follows:
```
ALTER QMGR CHLAUTH(ENABLED)
```

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:
```
SET CHLAUTH(' generic-channel-name ') TYPE(BLOCKUSER) USERLIST(userID1, userID2)
```
generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

The user list provided on a TYPE(BLOCKUSER) only applies to SVRCONN channels and not queue manager to queue manager channels.

userID1 and *userID2* are each the ID of a user that is to be prevented from using the channel. You can also specify the special value *MQADMIN to refer to privileged administrative users. For more information about privileged users, see "Privileged users" on page 718. For more information about *MQADMIN, see SET CHLAUTH.

Related information:

SET CHLAUTH

Mapping a remote queue manager to an MCAUSER user ID:

You can use a channel authentication record to set the MCAUSER attribute of a channel, according to the queue manager from which the channel is connecting.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

About this task

Optionally, you can restrict the IP addresses to which the rule applies.

Note that this technique does not apply to server-connection channels. If you specify the name of a server-connection channel in the following commands, it has no effect.

Procedure

- Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:

  ```
  SET CHLAUTH(' generic-channel-name ') TYPE (QMGRMAP) QMNAME(generic-partner-qmgr-name
  ) USERSRC(MAP) MCAUSER(user)
  ```

  generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

  generic-partner-qmgr-name is either the name of the queue manager, or a pattern including the asterisk (*) symbol as a wildcard that matches the queue manager name.

  user is the user ID to be used for all connections from the specified queue manager.
- To restrict this command to certain IP addresses, include the **ADDRESS** parameter, as follows:

  ```
  SET CHLAUTH(' generic-channel-name ') TYPE (QMGRMAP) QMNAME(generic-partner-qmgr-name
  ) USERSRC(MAP) MCAUSER(user) ADDRESS(generic-ip-address)
  ```

  generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

  generic-ip-address is either a single address, or a pattern including the asterisk (*) symbol as a wildcard or the hyphen (-) to indicate a range, that matches the address. For more information about generic IP addresses, see Generic IP addresses.

Related information:
SET CHLAUTH

Mapping a client asserted user ID to an MCAUSER user ID:

You can use a channel authentication record to change the MCAUSER attribute of a server-connection channel, according to the original user ID received from a client.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

About this task

Note that this technique applies only to server-connection channels. It has no effect on other channel types.

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record** . For example, you can issue the MQSC command:

```
SET CHLAUTH(' generic-channel-name ') TYPE (USERMAP) CLNTUSER(client-user-name) USERSRC(MAP) MCAUSER(user)
```

generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

client-user-name is the user ID asserted by the client.

user is the user ID to be used instead of the client user name.

Related information:
SET CHLAUTH

Mapping an SSL or TLS Distinguished Name to an MCAUSER user ID:

You can use a channel authentication record to set the MCAUSER attribute of a channel, according to the Distinguished Name (DN) received.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:

```
SET CHLAUTH('generic-channel-name') TYPE (SSLPEERMAP)
SSLPEER(generic-ssl-peer-name) SSLCERTI(generic-issuer-name)
USERSRC(MAP) MCAUSER(user)
```

generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

generic-ssl-peer-name is a string following the standard IBM MQ rules for SSLPEER values. See IBM MQ rules for SSLPEER values.

user is the user ID to be used for all connections using the specified DN.

generic-issuer-name refers to the Issuer DN of the certificate to match. This parameter is optional but you should use it, to avoid spuriously matching the wrong certificate, if multiple certificate authorities are in use.

Related information:

SET CHLAUTH

Blocking access from a remote queue manager:

You can use a channel authentication record to prevent a remote queue manager from starting channels.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

About this task

Note that this technique does not apply to server-connection channels. If you specify the name of a server-connection channel in the following command, it has no effect.

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:

```
SET CHLAUTH(' generic-channel-name ') TYPE(QMGRMAP) QMNAME(' generic-partner-qmgr-name ') USERSRC(NOACCESS)
```

generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

generic-partner-qmgr-name is either the name of the queue manager, or a pattern including the asterisk (*) symbol as a wildcard that matches the queue manager name.

Related information:

SET CHLAUTH

Blocking access for a client asserted user ID:

You can use a channel authentication record to prevent a client asserted user ID from starting channels.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

About this task

Note that this technique applies only to server-connection channels. It has no effect on other channel types.

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:

```
SET CHLAUTH(' generic-channel-name ') TYPE(USERMAP) CLNTUSER(' client-user-name ') USERSRC(NOACCESS)
```

generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

client-user-name is the user ID asserted by the client.

Related information:

SET CHLAUTH

Blocking access for an SSL Distinguished Name:

You can use a channel authentication record to prevent an SSL Distinguished Name (DN) from starting channels.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:

```
SET CHLAUTH('generic-channel-name') TYPE(SSLPEERMAP)
SSLPEER('generic-ssl-peer-name') SSLCERTI(generic-issuer-name)
USERSRC(NOACCESS)
```

generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

generic-ssl-peer-name is a string following the standard IBM MQ rules for SSLPEER values. See IBM MQ rules for SSLPEER values.

generic-issuer-name refers to the Issuer DN of the certificate to match. This parameter is optional but you should use it, to avoid spuriously matching the wrong certificate, if multiple certificate authorities are in use.

Related information:

SET CHLAUTH

Mapping an IP address to an MCAUSER user ID:

You can use a channel authentication record to set the MCAUSER attribute of a channel, according to the IP address from which the connection is received.

Before you begin

Ensure that channel authentication records are enabled as follows:

```
ALTER QMGR CHLAUTH(ENABLED)
```

Procedure

Set a channel authentication record using the MQSC command **SET CHLAUTH**, or the PCF command **Set Channel Authentication Record**. For example, you can issue the MQSC command:

```
SET CHLAUTH(' generic-channel-name ') TYPE(ADDRESSMAP) ADDRESS(' generic-ip-address ') USERSRC(MAP) MCAUSER(user)
```

generic-channel-name is either the name of a channel to which you want to control access, or a pattern including the asterisk (*) symbol as a wildcard that matches the channel name.

user is the user ID to be used for all connections using the specified DN.

generic-ip-address is either the address from which the connection is being made, or a pattern including the asterisk (*) as a wildcard or the hyphen (-) to indicate a range, that matches the address.

Related information:

SET CHLAUTH

Disabling remote access to the queue manager

If you do not want client applications to connect to your queue manager, disable remote access to it.

About this task

Prevent client applications connecting to the queue manager in one of the following ways:

Procedure

- Delete all server-connection channels using the MQSC command **`DELETE CHANNEL`**.
- Set the message channel agent user identifier (MCAUSER) of the channel to a user ID with no access rights, using the MQSC command **`ALTER CHANNEL`**.

Setting up connection security

Grant the authority to connect to the queue manager to each user or group of users with a business need to do so.

About this task

To set up connection security, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **`SET AUTHREC`** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -t qmgr -g GroupName +connect
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ('QMgrName') OBJTYPE(*MQM) USER('GroupName') AUT(*CONNECT)
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQCONN QMgrName.BATCH UACC(NONE)
  PERMIT QMgrName.BATCH CLASS(MQCONN) ID(GroupName) ACCESS(READ)
  RDEFINE MQCONN QMgrName.CICS UACC(NONE)
  PERMIT QMgrName.CICS CLASS(MQCONN) ID(GroupName) ACCESS(READ)
  RDEFINE MQCONN QMgrName.IMS UACC(NONE)
  PERMIT QMgrName.IMS CLASS(MQCONN) ID(GroupName) ACCESS(READ)
  RDEFINE MQCONN QMgrName.CHIN UACC(NONE)
  PERMIT QMgrName.CHIN CLASS(MQCONN) ID(GroupName) ACCESS(READ)
  ```

  These commands give authority to connect for batch, CICS, IMS and the channel initiator (CHIN). If you do not use a particular type of connection, omit the relevant commands. The variable names have the following meanings:

  QMgrName
  : The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  : The name of the object or generic profile for which to change authorizations.

  GroupName
  : The name of the group to be granted access.

Connection security profiles for the channel initiator

Controlling user access to queues

You want to control application access to queues. Use this topic to determine what actions to take.

For each true statement in the first column, take the action indicated in the second column.

Statement	Action
The application gets messages from a queue	See “Granting authority to get messages from queues”
The application sets context	See “Granting authority to set context” on page 770
The application passes context	See “Granting authority to pass context” on page 770
The application puts messages on a clustered queue	See “Authorizing putting messages on remote cluster queues” on page 814
The application puts messages on a local queue	See “Granting authority to put messages to a local queue” on page 771
The application puts messages on a model queue	See “Granting authority to put messages to a model queue” on page 772
The application puts messages on a remote queue	See “Granting authority to put messages to a remote cluster queue” on page 773

Granting authority to get messages from queues:

Grant the authority to get messages from a queue or set of queues, to each group of users with a business need for it.

About this task

To grant the authority to get messages from some queues, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +get
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*GET) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
  PERMIT QMgrName. ObjectProfile CLASS(MQADMIN) ID(GroupName) ACCESS(UPDATE)
  ```

  The variable names have the following meanings:

  QMgrName
  : The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  : The name of the object or generic profile for which to change authorizations.

GroupName
: The name of the group to be granted access.

Granting authority to set context:

Grant the authority to set context on a message that is being put, to each group of users with a business need for it.

About this task

To grant the authority to set context on some queues, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue one of the following commands:
  - To set identity context only:
    ```
    setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +setid
    ```
  - To set all context:
    ```
    setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +setall
    ```

  Note: To use `setid` or `setall` authority, authorizations must be granted on both the appropriate queue object and also on the queue manager object.
- For IBM i, issue one of the following commands:
  - To set identity context only:
    ```
    GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*SETID) MQMNAME(' QMgrName ')
    ```
  - To set all context:
    ```
    GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*SETALL) MQMNAME(' QMgrName ')
    ```
- For z/OS, issue one of the following sets of commands:
  - To set identity context only:
    ```
    RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
    PERMIT QMgrName. ObjectProfile CLASS(MQQUEUE) ID(GroupName) ACCESS(UPDATE)
    ```
  - To set all context:
    ```
    RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
    PERMIT QMgrName. ObjectProfile CLASS(MQQUEUE) ID(GroupName) ACCESS(CONTROL)
    ```

  The variable names have the following meanings:

  QMgrName
  : The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  : The name of the object or generic profile for which to change authorizations.

  GroupName
  : The name of the group to be granted access.

Granting authority to pass context:

Grant the authority to pass context from a retrieved message to one that is being put, to each group of users with a business need for it.

About this task

To grant the authority to pass context on some queues, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue one of the following commands:
  - To pass identity context only:
    ```
    setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +passid
    ```
  - To pass all context:
    ```
    setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +passall
    ```
- For IBM i, issue one of the following commands:
  - To pass identity context only:
    ```
    GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*PASSID) MQMNAME(' QMgrName ')
    ```
  - To pass all context:
    ```
    GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*PASSALL) MQMNAME(' QMgrName ')
    ```
- For z/OS, issue the following commands to pass identity context or all context:
  ```
  RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
  PERMIT QMgrName. ObjectProfile CLASS(MQQUEUE) ID(GroupName) ACCESS(UPDATE)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting authority to put messages to a local queue:

Grant the authority to put messages to a local queue or set of queues, to each group of users with a business need for it.

About this task

To grant the authority to put messages to some local queues, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +put
  ```
- For IBM i, issue the following command:

```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*PUT) MQMNAME(' QMgrName ')
```

- For z/OS, issue the following commands:

```
RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
PERMIT QMgrName. ObjectProfile CLASS(MQQUEUE) ID(GroupName) ACCESS(UPDATE)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

Granting authority to put messages to a model queue:

Grant the authority to put messages to a model queue or set of model queues, to each group of users with a business need for it.

About this task

Model queues are used to create dynamic queues. You must therefore grant authority to both the model and dynamic queues. To grant these authorities, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following commands:

```
setmqaut -m QMgrName -n ModelQueueName -t queue -g GroupName +put
setmqaut -m QMgrName -n ObjectProfile -t queue -g GroupName +put
```

- For IBM i, issue the following commands:

```
GRTMQMAUT OBJ(' ModelQueueName ') OBJTYPE(*Q) USER(GroupName) AUT(*PUT) MQMNAME(' QMgrName ')
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*Q) USER(GroupName) AUT(*PUT) MQMNAME(' QMgrName ')
```

- For z/OS, issue the following commands:

```
RDEFINE MQQUEUE QMgrName. ModelQueueName UACC(NONE)
PERMIT QMgrName. ModelQueueName CLASS(MQQUEUE) ID(GroupName) ACCESS(UPDATE)
RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
PERMIT QMgrName. ObjectProfile CLASS(MQQUEUE) ID(GroupName) ACCESS(UPDATE)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

ModelQueueName
The name of the model queue on which dynamic queues are based.

ObjectProfile
The name of the dynamic queue or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

Granting authority to put messages to a remote cluster queue:

Grant the authority to put messages to a remote cluster queue or set of queues, to each group of users with a business need for it.

About this task

To put a message on a remote cluster queue, you can either put it on a local definition of a remote queue, or a fully qualified remote queue. If you are using a local definition of a remote queue, you need authority to put to the local object: see “Granting authority to put messages to a local queue” on page 771. If you are using a fully qualified remote queue, you need authority to put to the remote queue. Grant this authority using the appropriate commands for your operating system.

The default behavior is to perform access control against the `SYSTEM.CLUSTER.TRANSMIT.QUEUE`. Note that this behavior applies, even if you are using multiple transmission queues.

The specific behavior described in this topic applies only when you have configured the **`ClusterQueueAccessControl`** attribute in the `qm.ini` file to be *RQMName*, as described in the Security stanza topic, and restarted the queue manager.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **`SET AUTHREC`** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -t rqmname -n ObjectProfile -g GroupName +put
  ```
  Note that you can use the *rqmname* object for remote cluster queues only.
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJTYPE(*RMTMQMNAME) OBJ('ObjectProfile') USER(GroupName) AUT(*PUT) MQMNAME('QMgrName')
  ```
  Note that you can use the RMTMQMNAME object for remote cluster queues only.
- For z/OS, issue the following commands:
  ```
  RDEFINE MQQUEUE QMgrName. ObjectProfile UACC(NONE)
  PERMIT QMgrName.QUEUE. ObjectProfile CLASS(MQQUEUE)
  ID(GroupName) ACCESS(UPDATE)
  ```
  Note that you can use the name of the remote queue manager (or queue-sharing group) for remote cluster queues only. The variable names have the following meanings:

  QMgrName
  : The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  : The name of the remote queue manager or generic profile for which to change authorizations.

  GroupName
  : The name of the group to be granted access.

Controlling user access to topics

You need to control the access of applications to topics. Use this topic to determine what actions to take.

For each true statement in the first column, take the action indicated in the second column.

Table 81. Controlling user access to topics

Statement	Action
The application publishes messages to a topic	See "Granting authority to publish messages to a topic"
The application subscribes to a topic	See "Granting authority to subscribe to topics"

Granting authority to publish messages to a topic:

Grant the authority to publish messages to a topic or set of topics, to each group of users with a business need for it.

About this task

To grant the authority to publish messages to some topics, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t topic -g GroupName +pub
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*TOPIC) USER(GroupName) AUT(*PUB) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQTOPIC QMgrName. ObjectProfile UACC(NONE)
  PERMIT QMgrName. ObjectProfile CLASS(MQTOPIC) ID(GroupName) ACCESS(UPDATE)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting authority to subscribe to topics:

Grant the authority to subscribe to a topic or set of topics, to each group of users with a business need for it.

About this task

To grant the authority to subscribe to some topics, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t topic -g GroupName +sub
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*TOPIC) USER(GroupName) AUT(*SUB) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQTOPIC QMgrName.SUBSCRIBE. ObjectProfile UACC(NONE)
  PERMIT QMgrName.SUBSCRIBE. ObjectProfile CLASS(MQTOPIC) ID(GroupName) ACCESS(UPDATE)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

  GroupName
  The name of the group to be granted access.

Granting authority to inquire on a queue manager

Grant the authority to inquire on a queue manager, to each group of users with a business need for it.

About this task

To grant the authority to inquire on a queue manager, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
  ```
  setmqaut -m QMgrName -n ObjectProfile -t qmgr -g GroupName +inq
  ```
- For IBM i, issue the following command:
  ```
  GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*MQM) USER(GroupName) AUT(*INQ) MQMNAME(' QMgrName ')
  ```
- For z/OS, issue the following commands:
  ```
  RDEFINE MQCMDS QMgrName. ObjectProfile UACC(NONE)
  PERMIT QMgrName. ObjectProfile CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
  ```

  These commands grant access to the specified queue manager. To permit the user to use the MQINQ command, issue the following commands:
  ```
  RDEFINE MQCMDS QMgrName.MQINQ.QMGR UACC(NONE)
  PERMIT QMgrName.MQINQ.QMGR CLASS(MQCMDS) ID(GroupName) ACCESS(READ)
  ```

  The variable names have the following meanings:

  QMgrName
  The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  The name of the object or generic profile for which to change authorizations.

GroupName
: The name of the group to be granted access.

Granting authority to access processes

Grant the authority to access a process or set of processes, to each group of users with a business need for it.

About this task

To grant the authority to access some processes, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
```
setmqaut -m QMgrName -n ObjectProfile -t process -g GroupName +all
```
- For IBM i, issue the following command:
```
GRTMQMAUT OBJ(' ObjectProfile ') OBJTYPE(*PRC) USER(GroupName) AUT(*ALL) MQMNAME(' QMgrName ')
```
- For z/OS, issue the following commands:
```
RDEFINE MQPROC QMgrName. ObjectProfile UACC(NONE)
PERMIT QMgrName. ObjectProfile CLASS(MQPROC) ID(GroupName) ACCESS(READ)
```

  The variable names have the following meanings:

  QMgrName
  : The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

  ObjectProfile
  : The name of the object or generic profile for which to change authorizations.

  GroupName
  : The name of the group to be granted access.

Granting authority to access namelists

Grant the authority to access a namelist or set of namelists, to each group of users with a business need for it.

About this task

To grant the authority to access some namelists, use the appropriate commands for your operating system.

On UNIX, Linux, Windows systems, and IBM i, you can also use the SET AUTHREC command.

Note: On IBM MQ Appliance you can use only the **SET AUTHREC** command.

Procedure

- For UNIX, Linux and Windows systems, issue the following command:
```
setmqaut -m QMgrName -n ObjectProfile -t namelist -g GroupName
+all
```
- For IBM i, issue the following command:

```
GRTMQMAUT OBJ('ObjectProfile
') OBJTYPE(*NMLIST) USER(GroupName) AUT(*ALL) MQMNAME('QMgrName')
```

- For z/OS, issue the following commands:

```
RDEFINE MQNLIST QMgrName.ObjectProfile UACC(NONE)
PERMIT QMgrName.ObjectProfile
CLASS(MQNLIST) ID(GroupName) ACCESS(READ)
```

The variable names have the following meanings:

QMgrName
The name of the queue manager. On z/OS, this value can also be the name of a queue-sharing group.

ObjectProfile
The name of the object or generic profile for which to change authorizations.

GroupName
The name of the group to be granted access.

Authority to administer IBM MQ on UNIX, Linux, and Windows systems

IBM MQ administrators can use all IBM MQ commands and grant authorities for other users. When administrators issue commands to remote queue managers, they must have the required authority on the remote queue manager. Further considerations apply to Windows systems.

IBM MQ administrators have authority to use all IBM MQ commands (including the commands to grant IBM MQ authorities for other users)

To be an IBM MQ administrator, you must be a member of a special group called the *mqm* group

Windows Alternatively, on Windows only, you can be a member of the Administrators group on Windows systems.

The mqm group is created automatically when IBM MQ is installed; add further users to the group to allow them to perform administration. All members of this group have access to all resources. This access can be revoked only by removing a user from the mqm group and issuing the REFRESH SECURITY command.

Administrators can use control commands to administer IBM MQ. One of these control commands is **setmqaut**, which is used to grant authorities to other users to enable them to access or control IBM MQ resources. The PCF commands for managing authority records are available to non-administrators who have been granted dsp and chg authorities on the queue manager. For more information about managing authorities using PCF commands, see Programmable Command Formats.

Administrators must have the required authorities for the MQSC commands to be processed by the remote queue manager. The IBM MQ Explorer issues PCF commands to perform administration tasks. Administrators require no additional authorities to use the IBM MQ Explorer to administer a queue manager on the local system. When the IBM MQ Explorer is used to administer a queue manager on another system, administrators must have the required authorities for the PCF commands to be processed by the remote queue manager.

Attention: From IBM MQ Version 8.0, you do not have to be an administrator to use the control command **runmqsc**, that issues IBM MQ Script (MQSC) commands.

When **runmqsc** is used in indirect mode to send MQSC commands to a remote queue manager, each MQSC command is encapsulated within an Escape PCF command.

For more information about authority checks when PCF and MQSC commands are processed, see the following topics:

- For PCF commands that operate on queue managers, queues, processes, namelists, and authentication information objects, see Authority to work with IBM MQ objects. Refer to this section for the equivalent MQSC commands encapsulated within Escape PCF commands.
- For PCF commands that operate on channels, channel initiators, listeners, and clusters, see Channel security.
- For PCF commands that operate on authority records, see Authority checking for PCF commands
- z/OS For MQSC commands that are processed by the command server on IBM MQ for z/OS, see Command security and command resource security on z/OS.

Additionally, on Windows systems, the SYSTEM account has full access to IBM MQ resources.

On UNIX and Linux platforms, a special user ID of mqm is also created, for use by the product only. It must never be available to non-privileged users. All IBM MQ objects are owned by user ID mqm.

On Windows systems, members of the Administrators group can also administer any queue manager, as can the SYSTEM account. You can also create a domain mqm group on the domain controller that contains all privileged user IDs active within the domain, and add it to the local mqm group. Some commands, for example **`crtmqm`**, manipulate authorities on IBM MQ objects and so need authority to work with these objects (as described in the following sections). Members of the mqm group have authority to work with all objects, but there might be circumstances on Windows systems when authority is denied if you have a local user and a domain-authenticated user with the same name. This is described in "Principals and groups" on page 782.

Windows versions with a User Account Control (UAC) feature restricts the actions users can perform on certain operating system facilities, even if they are members of the Administrators group. If your userid is in the Administrators group but not the mqm group you must use an elevated command prompt to issue IBM MQ admin commands such as **`crtmqm`**, otherwise the error `AMQ7077: You are not authorized to perform the requested operation` is generated. To open an elevated command prompt, right-click the start menu item, or icon, for the command prompt, and select **Run as administrator**.

You do not need to be a member of the mqm group to take the following actions:

- Issue commands from an application program that issues PCF commands, or MQSC commands within an Escape PCF command, unless the commands manipulate channel initiators. (These commands are described in "Protecting channel initiator definitions" on page 487).
- Issue MQI calls from an application program (unless you want to use the fast path bindings on the **MQCONNX** call).
- Use the **crtmqcvx** command to create a fragment of code that performs data conversion on data type structures.
- Use the **dspmq** command to display queue managers.
- Use the **dspmqtrc** command to display IBM MQ formatted trace output.

A 12 character limitation applies to both group and user IDs.

UNIX and Linux platforms generally restrict the length of a user ID to 12 characters. AIX Version 5.3 has raised this limit but IBM MQ continues to observe a 12 character restriction on all UNIX and Linux platforms. If you use a user ID of greater than 12 characters, IBM MQ replaces it with the value `UNKNOWN` . Do not define a user ID with a value of `UNKNOWN` .

Managing the mqm group

Users in the mqm group are granted full administrative privileges over IBM MQ. For this reason, you should not enrol applications and ordinary users in the mqm group. The mqm group should contain the accounts of the IBM MQ administrators only.

These tasks are described in:
- Creating and managing groups on Windows
- Creating and managing groups on HP-UX
- Creating and managing groups on AIX
- Creating and managing groups on Solaris
- Creating and managing groups on Linux

If your domain controller runs on Windows 2000 or Windows 2003, your domain administrator might have to set up a special account for IBM MQ to use. This is described in the Configuring IBM MQ accounts.

Authority to work with IBM MQ objects on UNIX, Linux and Windows systems

All objects are protected by IBM MQ, and principals must be given appropriate authority to access them. Different principals need different access rights to different objects.

Queue managers, queues, process definitions, namelists, channels, client connection channels, listeners, services, and authentication information objects are all accessed from applications that use MQI calls or PCF commands. These resources are all protected by IBM MQ, and applications need to be given permission to access them. The entity making the request might be a user, an application program that issues an MQI call, or an administration program that issues a PCF command. The identifier of the requester is referred to as the *principal*.

Different groups of principals can be granted different types of access authority to the same object. For example, for a specific queue, one group might be allowed to perform both put and get operations; another group might be allowed only to browse the queue (**MQGET** with browse option). Similarly, some groups might have put and get authority to a queue, but not be allowed to alter attributes of the queue or delete it.

Some operations are particularly sensitive and should be limited to privileged users. For example:
- Accessing some special queues, such as transmission queues or the command queue SYSTEM.ADMIN.COMMAND.QUEUE
- Running programs that use full MQI context options
- Creating and deleting application queues

Full access permission to an object is automatically given to the user ID that created the object and to all members of the mqm group (and to the members of the local Administrators group on Windows systems).

Related concepts:

"Authority to administer IBM MQ on UNIX, Linux, and Windows systems" on page 777
IBM MQ administrators can use all IBM MQ commands and grant authorities for other users. When administrators issue commands to remote queue managers, they must have the required authority on the remote queue manager. Further considerations apply to Windows systems.

When security checks are made on UNIX, Linux and Windows systems

Security checks are typically made on connecting to a queue manager, opening or closing objects, and putting or getting messages.

The security checks made for a typical application are as follows:

Connecting to the queue manager (MQCONN or MQCONNX calls)

This is the first time that the application is associated with a particular queue manager. The queue manager interrogates the operating environment to discover the user ID associated with the application. IBM MQ then verifies that the user ID is authorized to connect to the queue manager and retains the user ID for future checks.

Users do not have to sign on to IBM MQ; IBM MQ assumes that users have signed on to the underlying operating system and have been authenticated by that.

Opening the object (MQOPEN or MQPUT1 calls)

IBM MQ objects are accessed by opening the object and issuing commands against it. All resource checks are performed when the object is opened, rather than when it is actually accessed. This means that the **MQOPEN** request must specify the type of access required (for example, whether the user wants only to browse the object or perform an update like putting messages onto a queue).

IBM MQ checks the resource that is named in the **MQOPEN** request. For an alias or remote queue object, the authorization used is that of the object itself, not the queue to which the alias or remote queue resolves. This means that the user does not need permission to access it. Limit the authority to create queues to privileged users. If you do not, users might bypass the normal access control simply by creating an alias. If a remote queue is referred to explicitly with both the queue and queue manager names, the transmission queue associated with the remote queue manager is checked.

The authority to a dynamic queue is based on that of the model queue from which it is derived, but is not necessarily the same. This is described in Note 1 on page 521.

The user ID used by the queue manager for access checks is the user ID obtained from the operating environment of the application connected to the queue manager. A suitably authorized application can issue an **MQOPEN** call specifying an alternative user ID; access control checks are then made on the alternative user ID. This does not change the user ID associated with the application, only that used for access control checks.

Putting and getting messages (MQPUT or MQGET calls)

No access control checks are performed.

Closing the object (MQCLOSE)

No access control checks are performed, unless the **MQCLOSE** results in a dynamic queue being deleted. In this case, there is a check that the user ID is authorized to delete the queue.

Subscribing to a topic (MQSUB)

When an application subscribes to a topic, it specifies the type of operation that it needs to perform. It is either creating a new subscription, altering an existing subscription, or resuming an existing subscription without changing it. For each type of operation, the queue manager checks that the user ID that is associated with the application has the authority to perform the operation.

When an application subscribes to a topic, the authority checks are performed against the topic objects that are found in the topic tree at or above the point in the topic tree at which the application subscribed. The authority checks might involve checks on more than one topic object.

The user ID that the queue manager uses for the authority checks is the user ID obtained from the operating system when the application connects to the queue manager.

The queue manager performs authority checks on subscriber queues but not on managed queues.

How access control is implemented by IBM MQ on UNIX, Linux and Windows systems

IBM MQ uses the security services provided by the underlying operating system, using the object authority manager. IBM MQ supplies commands to create and maintain access control lists.

An access control interface called the Authorization Service Interface is part of IBM MQ. IBM MQ supplies an implementation of an access control manager (conforming to the Authorization Service Interface) known as the *object authority manager (OAM)*. This is automatically installed and enabled for each queue manager you create, unless you specify otherwise (as described in "Preventing security access checks on Windows, UNIX and Linux systems" on page 744). The OAM can be replaced by any user or vendor written component that conforms to the Authorization Service Interface.

The OAM exploits the security features of the underlying operating system, using operating system user and group IDs. Users can access IBM MQ objects only if they have the correct authority. "Controlling access to objects by using the OAM on UNIX, Linux and Windows systems" on page 735 describes how to grant and revoke this authority.

The OAM maintains an access control list (ACL) for each resource that it controls. Authorization data is stored on a local queue called SYSTEM.AUTH.DATA.QUEUE. Access to this queue is restricted to users in the mqm group, and additionally on Windows, to users in the Administrators group, and users logged in with the SYSTEM ID. User access to the queue cannot be changed.

IBM MQ supplies commands to create and maintain access control lists. For more information on these commands, see "Controlling access to objects by using the OAM on UNIX, Linux and Windows systems" on page 735.

IBM MQ passes the OAM a request containing a principal, a resource name, and an access type. The OAM grants or rejects access based on the ACL that it maintains. IBM MQ follows the decision of the OAM; if the OAM cannot make a decision, IBM MQ does not allow access.

Identifying the user ID on Windows, UNIX and Linux systems

The object authority manager identifies the principal that is requesting access to a resource. The user ID used as the principal varies according to context.

The object authority manager (OAM) must be able to identify who is requesting access to a particular resource. IBM MQ uses the term *principal* to refer to this identifier. The principal is established when the application first connects to the queue manager; it is determined by the queue manager from the user ID associated with the connecting application. (If the application issues XA calls without connecting to the queue manager, then the user ID associated with the application that issues the xa_open call is used for authority checks by the queue manager.)

On UNIX and Linux systems, the authorization routines checks either the real (logged-in) user ID, or the effective user ID associated with the application. The user ID checked can be dependent on the bind type, for details see Installable services.

IBM MQ propagates the user ID received from the system in the message header (MQMD structure) of each message as identification of the user. This identifier is part of the message context information and is described in "Context authority on UNIX, Linux and Windows systems" on page 784. Applications cannot alter this information unless they have been authorized to change context information.

Principals and groups

Principals can belong to groups. By granting resource access to groups rather than to individuals, you can reduce the amount of administration required. Access Control Lists (ACLs) are based on both groups and user IDs.

For example, you might define a group consisting of users who want to run a particular application. Other users can be given access to all the resources they require by adding their user ID to the appropriate group.

This process of defining and managing groups is described for particular platforms:
- Creating and managing groups on Windows
- Creating and managing groups on HP-UX
- Creating and managing groups on AIX
- Creating and managing groups on Solaris
- Creating and managing groups on Linux

A principal can belong to more than one group (its group set). It has the aggregate of all the authorities granted to each group in its group set. These authorities are cached, so any changes you make to the group membership of the principal are not recognized until the queue manager is restarted, unless you issue the MQSC command REFRESH SECURITY (or its PCF equivalent).

UNIX and Linux systems

ACLs are based on both user IDs and groups and you can use either for authorization.

With Version 8.0, you can use the *user-based model* for authorization, and this allows you to use both users and groups. However, when you specify a user in the setmqaut command, the new permissions apply to that user alone, and not any groups to which that user belongs.

See Installable services for more information.

When you are using the *group-based model* for authorization, the primary group to which the user ID belongs is included in the ACL.

The individual user ID is not included and authority is granted to all members of that group. Because of this, be aware that you can inadvertently change the authority of a principal by changing the authority of another principal in the same group.

All users are nominally assigned to the default user group `nobody` and by default, no authorizations are given to this group. You can change the authorization in the `nobody` group to grant access to IBM MQ resources to users without specific authorizations.

Do not define a user ID with the value `UNKNOWN`. The value `UNKNOWN` is used when a user ID is too long, so arbitrary user IDs would use the access authorities of UNKNOWN.

User IDs can contain up to 12 characters and group names up to 12 characters.

Windows systems

ACLs are based on both user IDs and groups. Checks are the same as for UNIX systems. You can have different users on different domains with the same user ID. IBM MQ permits user IDs to be qualified by a domain name so that these users can be given different levels of access.

The group name can optionally include a domain name, specified in the following formats:

`GroupName@domain` *`domain_name\group_name`*

Global groups are checked by the OAM in two cases only:
1. The queue manager security stanza includes the setting: `GroupModel=GlobalGroups`. See Security.
2. The queue manager is using an alternative security access group. See **`crtmqm`** .

User IDs can contain up to 20 characters, domain names up to 15 characters, and group names up to 64 characters.

The OAM first checks the local security database, then the database of the primary domain, and finally the database of any trusted domains. The first user ID encountered is used by the OAM for checking. Each of these user IDs might have different group memberships on a particular computer.

Some control commands (for example, **crtmqm**) change authorities on IBM MQ objects using the object authority manager (OAM). The OAM searches the security databases in the order given in the preceding paragraph to determine the authority rights for a particular user ID. As a result, the authority determined by the OAM might override the fact that a user ID is a member of the local mqm group. For example, if you issue the **crtmqm** command from a user ID authenticated by a domain controller that has membership of the local mqm group through a global group, the command fails if the system has a local user with the same name who is not in the local mqm group.

Windows security identifiers (SIDs)

IBM MQ on Windows uses the SID where it is available. If a Windows SID is not supplied with an authorization request, IBM MQ identifies the user based on the user name alone, but this might result in the wrong authority being granted.

On Windows systems, the security identifier (SID) is used to supplement the user ID. The SID contains information that identifies the full user account details on the Windows security account manager (SAM) database where the user is defined. When a message is created on IBM MQ for Windows, IBM MQ stores the SID in the message descriptor. When IBM MQ on Windows performs authorization checks, it uses the SID to query the full information from the SAM database. (The SAM database in which the user is defined must be accessible for this query to succeed.)

By default, if a Windows SID is not supplied with an authorization request, IBM MQ identifies the user based on the user name alone. It does this by searching the security databases in the following order:

1. The local security database
2. The security database of the primary domain
3. The security database of trusted domains

If the user name is not unique, incorrect IBM MQ authority might be granted. To prevent this problem, include an SID in each authorization request; the SID is used by IBM MQ to establish user credentials.

To specify that all authorization requests must include an SID, use **regedit** . Set the SecurityPolicy to NTSIDsRequired.

Alternate-user authority on UNIX, Linux and Windows systems

You can specify that a user ID can use the authority of another user when accessing an IBM MQ object. This is called *alternate-user authority*, and you can use it on any IBM MQ object.

Alternate-user authority is essential where a server receives requests from a program and wants to ensure that the program has the required authority for the request. The server might have the required authority, but it needs to know whether the program has the authority for the actions it has requested.

For example, assume that a server program running under user ID PAYSERV retrieves a request message from a queue that was put on the queue by user ID USER1. When the server program gets the request message, it processes the request and puts the reply back into the reply-to queue specified with the request message. Instead of using its own user ID (PAYSERV) to authorize opening the reply-to queue, the server can specify a different user ID, in this case, USER1. In this example, you can use alternate-user authority to control whether PAYSERV is allowed to specify USER1 as an alternate-user ID when it opens the reply-to queue.

The alternate-user ID is specified on the **`AlternateUserId`** field of the object descriptor.

Context authority on UNIX, Linux and Windows systems

Context is information that applies to a particular message and is contained in the message descriptor, MQMD, which is part of the message. Applications can specify the context data when either an **MQOPEN** or **MQPUT** call is made.

The context information comes in two sections:

Identity section
Who the message came from. It consists of the `UserIdentifier`, `AccountingToken`, and `ApplIdentityData` fields.

Origin section
Where the message came from, and when it was put onto the queue. It consists of the `PutApplType`, `PutApplName`, `PutDate`, `PutTime`, and `ApplOriginData` fields.

Applications can specify the context data when either an **MQOPEN** or **MQPUT** call is made. This data might be generated by the application, passed on from another message, or generated by the queue manager by default. For example, context data can be used by server programs to check the identity of the requester, testing whether the message came from an application running under an authorized user ID.

A server program can use the `UserIdentifier` to determine the user ID of an alternative user. You use context authorization to control whether the user can specify any of the context options on any **MQOPEN** or **MQPUT1** call.

See Controlling context information for information about the context options, and Overview for MQMD for descriptions of the message descriptor fields relating to context.

Implementing access control in security exits

You can implement access control in a security exit by use of the MCAUserIdentifier or the object authority manager.

MCAUserIdentifier

Every instance of a channel that is current has an associated channel definition structure, MQCD. The initial values of the fields in MQCD are determined by the channel definition that is created by an IBM MQ administrator. In particular, the initial value of one of the fields, *MCAUserIdentifier*, is determined by the value of the MCAUSER parameter on the DEFINE CHANNEL command, or by the equivalent to MCAUSER if the channel definition is created in another way.

The MQCD structure is passed to a channel exit program when it is called by an MCA. When a security exit is called by an MCA, the security exit can change the value of *MCAUserIdentifier*, replacing any value that was specified in the channel definition.

On IBM i, UNIX, Linux and Windows systems, unless the value of *MCAUserIdentifier* is blank, the queue manager uses the value of *MCAUserIdentifier* as the user ID for authority checks when an MCA attempts to access the queue manager's resources after it has connected to the queue manager. If the value of *MCAUserIdentifier* is blank, the queue manager uses the default user ID of the MCA instead. This applies to RCVR, RQSTR, CLUSRCVR and SVRCONN channels. For sending MCAs, the default user ID is always used for authority checks, even if the value of *MCAUserIdentifier* is not blank.

On z/OS, the queue manager might use the value of *MCAUserIdentifier* for authority checks, provided it is not blank. For receiving MCAs and server connection MCAs, whether the queue manager uses the value of *MCAUserIdentifier* for authority checks depends on:
- The value of the PUTAUT parameter in the channel definition
- The RACF profile used for the checks
- The access level of the channel initiator address space user ID to the RESLEVEL profile

For sending MCAs, it depends on:
- Whether the sending MCA is a caller or a responder
- The access level of the channel initiator address space user ID to the RESLEVEL profile

The user ID that a security exit stores in *MCAUserIdentifier* can be acquired in various ways. Here are some examples:
- Provided there is no security exit at the client end of an MQI channel, a user ID associated with the IBM MQ client application flows from the client connection MCA to the server connection MCA when the client application issues an MQCONN call. The server connection MCA stores this user ID in the *RemoteUserIdentifier* field in the channel definition structure, MQCD. If the value of *MCAUserIdentifier* is blank at this time, the MCA stores the same user ID in *MCAUserIdentifier*. If the MCA does not store the user ID in *MCAUserIdentifier*, a security exit can do it later by setting *MCAUserIdentifier* to the value of *RemoteUserIdentifier*.

  If the user ID that flows from the client system is entering a new security domain and is not valid on the server system, the security exit can substitute the user ID for one that is valid and store the substituted user ID in *MCAUserIdentifier*.
- The user ID can be sent by the partner security exit in a security message.

  On a message channel, a security exit called by the sending MCA can send the user ID under which the sending MCA is running. A security exit called by the receiving MCA can then store the user ID in *MCAUserIdentifier*. Similarly, on an MQI channel, a security exit at the client end of the channel can send the user ID associated with the IBM MQ MQI client application. A security exit at the server end of the channel can then store the user ID in *MCAUserIdentifier*. As in the previous example, if the user

ID is not valid on the target system, the security exit can substitute the user ID for one that is valid and store the substituted user ID in *MCAUserIdentifier*.

If a digital certificate is received as part of the identification and authentication service, a security exit can map the Distinguished Name in the certificate to a user ID that is valid on the target system. It can then store the user ID in *MCAUserIdentifier*.

- If SSL is used on the channel, the partner's Distinguished Name (DN) is passed to the exit in the SSLPeerNamePtr field of the MQCD, and the DN of the issuer of that certificate is passed to the exit in the SSLRemCertIssNamePtr field of the MQCXP.

For more information about the *MCAUserIdentifier* field, the channel definition structure, MQCD, and the channel exit parameter structure, MQCXP, see Channel-exit calls and data structures. For more information about the user ID that flows from a client system on an MQI channel, see Access control.

Note: Security exit applications constructed prior to the release of IBM MQ v7.1 may require updating. For more information see Channel security exit programs.

IBM MQ object authority manager user authentication

On IBM MQ MQI client connections, security exits can be used to modify or create the MQCSP structure used in object authority manager (OAM) user authentication. This is described in Channel-exit programs for messaging channels

Implementing access control in message exits

You might need to use a message exit to substitute one user ID with another.

Consider a client application that sends a message to a server application. The server application can extract the user ID from the *UserIdentifier* field in the message descriptor and, provided it has alternate user authority, ask the queue manager to use this user ID for authority checks when it accesses IBM MQ resources on behalf of the client.

If the PUTAUT parameter is set to CTX (or ALTMCA on z/OS) in the channel definition, the user ID in the *UserIdentifier* field of each incoming message is used for authority checks when the MCA opens the destination queue.

In certain circumstances, when a report message is generated, it is put using the authority of the user ID in the *UserIdentifier* field of the message causing the report. In particular, confirm-on-delivery (COD) reports and expiration reports are always put with this authority.

Because of these situations, it might be necessary to substitute one user ID for another in the *UserIdentifier* field as a message enters a new security domain. This can be done by a message exit at the receiving end of the channel. Alternatively, you can ensure that the user ID in the *UserIdentifier* field of an incoming message is defined in the new security domain.

If an incoming message contains a digital certificate for the user of the application that sent the message, a message exit can validate the certificate and map the Distinguished Name in the certificate to a user ID that is valid on the receiving system. It can then set the *UserIdentifier* field in the message descriptor to this user ID.

If it is necessary for a message exit to change the value of the *UserIdentifier* field in an incoming message, it might be appropriate for the message exit to authenticate the sender of the message at the same time. For more details, see "Identity mapping in message exits" on page 720.

Implementing access control in the API exit and API-crossing exit

An API or API-crossing exit can provide access controls to supplement those provided by IBM MQ. In particular, the exit can provide access control at the message level. The exit can ensure that an application puts on a queue, or gets from a queue, only those messages that satisfy certain criteria.

Consider the following examples:

- A message contains information about an order. When an application attempts to put a message on a queue, an API or API-crossing exit can check that the total value of the order is less than some prescribed limit.
- Messages arrive on a destination queue from remote queue managers. When an application attempts to get a message from the queue, an API or API-crossing exit can check that the sender of the message is authorized to send a message to the queue.

Overview of LDAP authorization

V 8.0.0.2

An overview of how you use LDAP authorization to remove the need for a local user ID.

Commands that handle authorization configuration, such as setmqaut and DISPLAY AUTHREC, can now process Distinguished Names. Previously, users were authenticated by comparing their credentials with the maximum available characters that exist for users and groups on the local operating system.

Attention: If you have run the DEFINE AUTHINFO command, you must restart the queue manager. If you do not restart the queue manager, the setmqaut command does not return the correct result.

If a user provides a user ID, rather than a Distinguished Name, the user ID is processed. For example, when there is an incoming message on a channel with PUTAUT(CTX), the characters in the user ID are mapped to an LDAP Distinguished Name, and the appropriate authorization checks are made.

Other commands such as DISPLAY CONN, continue to work with and show the actual value for the user ID, even though that user ID might not actually exist on the local OS.

When LDAP authorization is in place, the queue manager always uses the user model of security on UNIX platforms, regardless of the **SecurityPolicy** attribute in the `qm.ini` file. So, setting permissions for an individual user affects only that user, and not anyone else who belongs to any of that user's groups.

As with the OS model, a user still has the combined authority that has been assigned to both the individual and to all of the groups (if any) to which the user belongs.

For example, assume that the following records have been defined in an LDAP repository.

- In the **inetOrgPerson** class:

```
dn="cn=JohnDoe, ou=users, o=yourcompany, c=yourcountry"
        email=JohnDoe1@yourcompany.com [longer than 12 characters]
        shortu=jodoe
        Phone=1234567
```

- In the **groupOfNames** class:

```
dn="cn=Application Group A, ou=groups, o=yourcompany, c=yourcountry"
        longname=ApplicationGroupA [longer than 12 characters]
        members="cn=JaneDoe, ou=users, o=yourcompany, c=yourcountry",
                "cn=JohnDoe, ou=users, o=yourcompany, c=yourcountry"
```

For authentication purposes, a queue manager using this LDAP server must have been defined so that its CONNAUTH value points at an AUTHINFO object of type IDPWLDAP, and whose relevant name-resolution attributes are probably set as follows:

```
USRFIELD(email) SHORTUSR(shortu)
BASEDNU(ou=users,o=yourcompany,c=yourcountry) CLASSUSR(inetOrgPerson)
```

Given this configuration for authentication, an application can fill in the CSPUserID field, used within the MQCNO call, with either of the following sets of values:

```
" cn=JohnDoe ", " JohnDoe1@yourcompany.com ", " email=JohnDoe1@yourcompany.com "
```

or

```
" cn=JohnDoe, ou=users, o=ibm, c=uk ", " shortu=jodoe "
```

In either case, the system can use the supplied values to authenticate the OS context of " `jodoe`".

Enabling LDAP authorization on the supported platforms

LDAP authorization is available on the following platforms:
- UNIX
- IBM i

Important:

To enable configuration of the new authorization model, you must firstly change the command level of the queue manager to be higher than the IBM MQ Version 8.0.0.0 general availability level of *800*.

You have to do this explicitly. The change is not done automatically by installation of the fix pack. For example:

```
strmqm -e CMDLEVEL=802 <qmname>
strmqm <qmname>
```

If you set **`CMDLEVEL`** to *802*, you can rollback the fix pack, provided that you have not used the new function.

The queue manager command level controls whether or not configuration changes can be made that affect authorization. After this change you can see and modify the new attributes on the AUTHINFO object.

If you attempt to access the new AUTHINFO attributes from an upgraded code level, without also updating the command level, you receive an error message about needing to change the command level.

Note that the command level has no direct relationship to the Version, Release, Modification, Fix pack level.

Setting authorizations

V 8.0.0.2

How you use the short name or **`USRFIELD`** to set authorizations.

The approach of working with multiple formats, described in "Overview of LDAP authorization" on page 789, continues into the authorization commands, with a further extension that either the `shortname` or the USRFIELD can be used in an unadorned fashion.

The character string specifies a particular attribute in the LDAP record when naming users (principals) for authorization.

Important: The character string must not contain the = character, because this character cannot be used in an operating system user ID.

If you pass a principal name to the OAM for authorization that is potentially a `shortname`, the character string must fit into 12 characters. The mapping algorithm first tries to resolve it to a DN using the SHORTUSR attribute in its LDAP query.

If that fails with an UNKNOWN_ENTITY error, or if the given string cannot possibly be a `shortname`, a further attempt is made using the USRFIELD attribute to construct the LDAP query.

Attention: If you have run the DEFINE AUTHINFO command, you must restart the queue manager. If you do not restart the queue manager, the setmqaut command does not return the correct result.

For processing user authorizations, using the setmqaut command, the following are all equivalent.

Table 82. User authorization settings

Command	Note
`setmqaut -m QM -t qmgr -p jodoe +connect`	This is a flat, unqualified name, resolved through SHORTUSR.
`setmqaut -m QM -t qmgr -pJohnDoe1@yourcompany.com +connect`	Also a flat, unqualified name, resolving via USRFIELD to the same entity.
`setmqaut -m QM -t qmgr -p email=JohnDoe1@yourcompany.com +connect`	Using a named attribute.
`setmqaut -m QM -t qmgr -p "phone=1234567" +connect`	Using another named attribute which does not have to be any of those configured on the AUTHINFO object.

You can use the SET AUTHREC MQSC command as an alternative to the **setmqaut** command:

```
SET AUTHREC OBJTYPE(QMGR) PRINCIPAL('JohnDoe1@yourcompany.com') AUTHADD(connect)
```

or the Set Authority Record (MQCMD_SET_AUTH_REC) PCF command with the MQCACF_PRINCIPAL_ENTITY_NAMES element containing the string:

```
"cn=JohnDoe,ou=users,o=yourcompany,c=yourcountry"
```

When processing groups, there is no ambiguity about `shortname` processing, as there is no requirement to fit any form of a group name into 12-characters. Therefore, there is no equivalent of the SHORTUSR attribute for groups.

That means that the syntax examples described in Table 83 are valid, assuming that you have configured the AUTHINFO object with the extended attributes, and set to:

```
GRPFIELD(longname)
BASEDNG(ou=groups,o=yourcompany,c=yourcountry ) CLASSGRP(groupOfNames)
```

Table 83. Group authorization settings

Command	Note
`setmqaut -m QM -t qmgr -g ApplicationGroupA +connect`	Using GRPFIELD to resolve
`setmqaut -m QM -t qmgr -g longname=ApplicationGroupA +connect`	Naming a single attribute
`setmqaut -m QM -t qmgr -g "cn=Application Group A,ou=groups,o=yourcompany,c=yourcountry" +connect`	Using the full DN

You can use the SET AUTHREC MQSC command as an alternative to the preceding **setmqaut** command:

```
SET AUTHREC OBJTYPE(QMGR) GROUP('ApplicationGroupA')
      AUTHADD(connect)
```

or the Set Authority Record (MQCMD_SET_AUTH_REC) PCF command with the MQCACF_GROUP_ENTITY_NAMES element containing the string:

```
"ApplicationGroupA"
```

Important:

Whichever format you use to refer to a name, whether for user or group, it must be possible to derive a unique DN.

So, for example, you must not have two distinct records that both have "`shortu=jodoe`".

If a single unique DN cannot be determined, the OAM returns MQRC_UNKNOWN_ENTITY.

Displaying authorizations

V 8.0.0.2 V 8.0.0.2

Various methods of displaying authorization of users or groups.

dspmqaut command

The simplest method for displaying the authorizations available for a user or group is to use the dspmqaut command.

You can use a query on any of the syntax variations for identifying a user or group. Note that the command output repeats the identity in the format given on the command line. The output does not report on the full resolved DN.

For example:

```
dspmqaut -m QM -t qmgr -p johndoe
Entity johndoe has the following authorizations for object QM:
 connect
```

or

```
dspmqaut -m QM -t qmgr -p email=JohnDoe1@yourcompany.com
Entity email=JohnDoe1@yourcompany.com has the following authorizations for object QM:
 connect
```

dmpmqaut and dmpmqcfg commands

The dmpmqaut command, and its MQSC or PCF equivalents, can specify the principal or group in any of the supported formats, like the **setmqaut** tables described in “Setting authorizations” on page 790. However, unlike **dspmqaut**, the **dmpmqaut** command always reports the full DN.

```
dmpmqaut -m QM -t qmgr -p jodoe
------------------------------------
profile: self
object type:qmgr
entity:cn=JohnDoe, ou=users, o=yourcompany, c=yourcountry
entity type: principal
authority: connect
```

Similarly, the dmpmqcfg command, which does not have any filtering on the selected records, always shows the full DN in a format that can be replayed later.

```
dmpmqcfg -m QM -x authrec
------------------------------------
SET AUTHREC PROFILE(SELF) +
 PRINCIPAL('cn=JohnDoe, ou=users, o=yourcompany, c=yourcountry') +
 OBJTYPE(QMGR)
 AUTHADD(CONNECT)
```

LDAP authorization - other changes

V 8.0.0.2 V 8.0.0.2

A brief description of changes to the Message Queue Interface (MQI) and other MQSC and PCF commands that you need to be aware of when using LDAP authorization from IBM MQ Version 8.0.0, Fix Pack 2.

ADOPTCTX

There is no requirement for applications to provide authentication information, or for the ADOPTCTX attribute to be set to YES.

If an application does not explicitly authenticate, or if **ADOPTCTX** is set to NO for the active CONNAUTH object, the identity context associated with the application is taken from the operating system user ID.

When authorizations need to be applied, that context is mapped to an LDAP identity using the same rules as for the setmqaut commands.

Input parameters to MQI calls

MQOPEN, MQPUT1, and MQSUB have structures that allow an alternative user ID to be specified.

If those fields are used, the 12-character user ID is mapped to a DN using the same rules as on the **setmqaut**, **dmpmqaut**, and **dspmqaut** commands.

MQPUT and MQPUT1 also allow suitably authorized programs to set the MQMD UserIdentifier field. The value of this field is not policed during the PUT process, and can be set to any value.

As usual, however, the **UserIdentifier** value can be used for authorization at later stages of the message processing, for example when PUTAUT(CTX) is defined on a receiving channel.
